The only species is *Lavia frons*.

Meredith Happold

Lavia frons YELLOW-WINGED BAT

Fr. Mégaderme à ailes orangées; Ger. Gelbflügel-Fledermaus

Lavia frons (E. Geoffroy, 1810). Ann. Mus. Natn. Hist. Nat. Paris 15: 192. Senegal.

Lavia frons.

Taxonomy Originally *Megaderma frons*. Synonyms: *affinis*, *rex*. Subspecies: three of very dubious validity. Chromosome number: not known.

Description Medium-small microbat with noseleaf and very large interfemoral membrane but no tail; brightly coloured (grey with orange–yellow wings); ears enormous and partly joined; tragus bifid; noseleaf erect and comparatively long (19–26 mm). Sexes similar in colour; ♀♀ slightly larger, on average, than ♂♂. Pelage slightly shaggy; mid-dorsal hairs ca. 15 mm. Dorsal pelage bluish-grey to slate-grey, suffused with greenish-yellow on lower back; hairs unicoloured. Ventral pelage greyish-fawn; sometimes yellowish. Males produce yellow secretion from glands on lower back (Lang & Chapin 1917b), but both sexes have yellowish pelage on lower back. Head appears very large because of the long ears and noseleaf. Noseleaf

very long and erect (Figure 76c), 19–26 mm long (cf. 9–14 mm in *Cardioderma cor*). Ears orange–yellow, almost twice as long as head; basal halves joined by interaural membrane. Tragus bifid; outer lobe long and tapering to fine point, inner lobe much shorter (Figure 76e). Eyes very large for a microbat. Wings very broad, variegated bright yellow, orange and pale brown; colour fades after death. Interfemoral membrane yellowish-orange. Hindlimbs long. No tail.

Skull as in Figure 76g, i and k. Frontal shield comparatively flat and wide (cf. *C. cor*); minimum breadth 7.3 (6.8–7.9) mm, *n* = 10. For more details, see Vohnhof & Kalcounis (1999).

Geographic Variation Koopman (1994) and Simmons (2005) list three poorly defined subspecies, but they are of dubious validity:

L.f. affinis: Sudan, Chad, N Uganda and extreme NW DR Congo. FA: 57.3 (49–61) mm, *n* = 44.

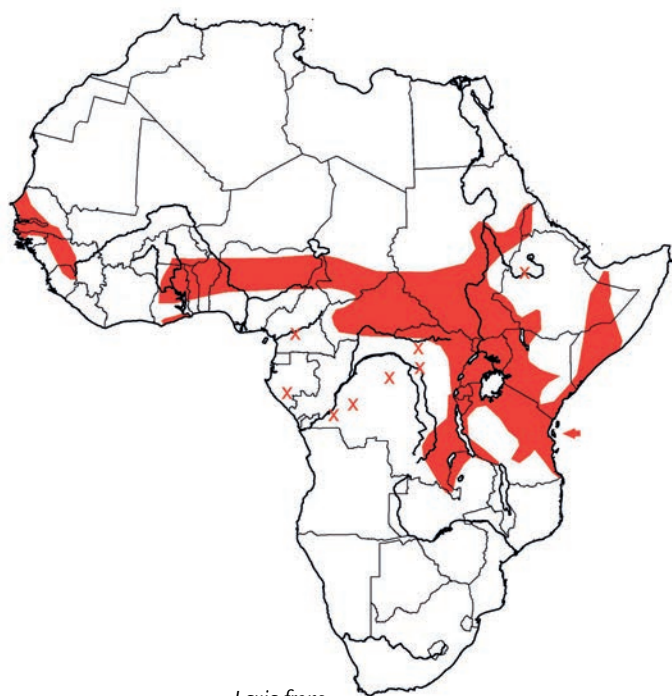

L.f. frons: western part of geographic range. FA: 59.3 (53–64) mm, *n* = 51.

L.f. rex: Ethiopia and southwards to N Malawi and westwards to E DR Congo. FA: 59.8 (56–65) mm, *n* = 25.

Similar Species There is only one other megadermatid in Africa:

Cardioderma cor. Noseleaf shorter (length 9–14 mm). Pelage grey or bluish-grey without yellow tinge. Frontal shield of skull strongly concave; minimum breadth narrower (5.3–6.2 mm).

Distribution Mainly Sudan Savanna, Guinea Savanna, Somalia–Masai, Coastal Forest Mosaic and Zambezi Woodland BZs, with some records in the Rainforest BZ and the Rainforest–Savanna Mosaics and two records in the Sahel Savanna BZ. Also recorded, but only very rarely, in Afromontane–Afroalpine BZ. Recorded disjunctly from Senegal to Eritrea and W Somalia (but absent from most of Ethiopia) and southwards to Gabon, DR Congo and Tanzania (including Zanzibar I.) with marginal records in C Zambia and N Malawi (Kock 1969a, Largen *et al.* 1974, Ansell 1978, Harrison 1982, Grubb *et al.* 1998 and others). The gap between 2°W and 11°W probably reflects insufficient collecting in that area. A record from Namibia (Andersen & Wroughton 1907 as *Vespertilio megalotis* Bechstein, 1800) is very dubious (D. Kock pers. comm.) and is not mapped.

Lavia frons

Habitat In the savanna zones from West Africa to eastern Africa, *L. frons* seems to occur mainly in woodland savannas with abundant acacias (Rosevear 1965, Verschuren 1966, Vaughan & Vaughan 1986). Also occurs in West African coastal mosaic, open degraded riverine forests in the Rainforest BZ of the central Congo Basin, East African Coastal Forest Mosaic and miombo woodland. In arid areas, *L. frons* is found in bush country surrounding lakes, marshes and along rivers (Lang & Chapin 1917a). Usually found below 1000 m. Apparently not found in closed rainforest, or at altitudes above 2000 m.

Abundance Uncertain; moderately common in museum collections.

Adaptations A well-known species. Wings very broad; aspect ratio very low; wing-loading medium; wing-tip rounded (Norberg & Rayner 1987). Flight fairly slow (mean speed 6.6 m/s), erratic and fluttering. Negotiates clutter with precise manoeuvrability. Roosts in foliage of trees throughout year. In Kenya, roosts in crowns of acacias, 5–10 m above ground. Basks in the sun on cool mornings and after rain, but usually roosts in shade and, during the day, moves from perch to perch, or into dense low shrubs, to find shadier positions (Vaughan 1987). To facilitate thermoregulation, at temperatures above 31 °C, blood vessels in the wings dilate and the wings are folded loosely and slightly away from the body (Vaughan 1987). Remains open-eyed and vigilant throughout the day, and flies to another perch if approached by hornbills (which prey on small vertebrates), other large birds and humans. Does not become torpid during day, and does not hibernate.

Foraging and Food Appears to be entirely insectivorous – unlike other megadermatids, *L. frons* is not known to include small vertebrates in its diet. Usually forages by opportunistic fly-catching, but occasionally flies from its perches to glean from the ground. Foraging is described in detail by Vaughan & Vaughan (1986).

Individuals hang from exposed perches, swivelling from side to side, flickering the ears, and raising the head up and down. Flying insects appear to be detected at long range by eyesight: the eyes have a tapetum lucidum, which implies enhanced night-vision, and it seems likely that *L. frons* can see insects silhouetted against the evening and night skies. The echolocation calls of *L. frons* (see below) would not allow long-range detection of prey, but may be used in the final stages of prey-catching. When prey is detected, individuals make a precise and very brief (typically three seconds) flight to intercept the prey, and then invariably returns to the perch before eating. There are no pursuits, and the energetic cost of foraging is minimal. During wet seasons, when insects are abundant, *L. frons* selects prey 1–2 cm long, which are searched for, and captured, near the perch and roughly on the same horizontal plane as the perch. When insects are scarce, individuals scan more than 90 degrees from ground level to high above, and attack any insect that will provide more energy than the cost of its capture. At such times, they will swoop down to take insects near the ground and also make towering flights into open spaces 20–30 m above the ground (perhaps to catch prey >2 cm in length). Throughout the year, foraging may occur during the day, but the main feeding period is after sundown. Most foraging is done from favoured perches along a particular route, which is exploited for several consecutive nights before a change is made. Individuals fly from perch to perch until a concentration of insects is located. In Kenya, *L. frons* occupies an exclusive feeding niche and exploits diurnal insects to a greater extent than other species of bat in the same area. In East Africa, this bat is closely associated with *Acacia tortilis*, which flowers and grows new leaves asynchronously in response to erratic dry-season rains: the trees attract insects that may be of crucial importance to *L. frons* during the dry seasons. In DR Congo, individuals have been observed at noon, perch-hunting insects in front of a grass fire, and they are often found roosting in trees and bushes fringing rivers, swamps and lakes where, perhaps, favoured insects are particularly common (Lang & Chapin 1917b). Feeds on a wide variety of very small to relatively large, soft and hard-shelled insects, including mosquitoes, flies, winged termites, butterflies, moths, grasshoppers and beetles.

Echolocation The echolocation calls are low-intensity broad bandwidth calls that provide detailed information about close objects, and are particularly suited to cluttered environments.

Social and Reproductive Behaviour Lives in monogamous pairs, in territories that are defended by the ♂ (Wickler & Uhrig 1969, Vaughan & Vaughan 1986). In Kenya, territories are 0.6–0.95 ha in area and contain 17–34 acacia trees (Vaughan & Vaughan 1986). Paired bats roost together, less than 1 m apart, and at least 20 m from the nearest neighbouring pair. Each pair has a primary roost (near the territorial boundary) where both bats spend most of the day and, although they may have moved to a shadier roost during the day, they return to the primary roost for a period of grooming, stretching and social interaction before beginning to forage. The ♂ leaves first, and patrols the territory for 10–15 min before the ♀ leaves. Evening patrols are stereotyped: the ♂ flies to sentinel posts in trees around the territorial boundary, each post being visited in a consistent sequence. Intruding conspecifics are attacked and driven away. Apparently, there is no territorial ‘song’

as in *C. cor*. Foraging begins after the evening patrol and is confined to the territory. When insects are abundant, the pair often forages together. When insects are scarce, they may forage apart but, if one finds a concentration of insects, the other may be attracted to the site. When this happens, the bats forage from separate perches and interference is avoided. More often than not, it is the ♀ which joins the ♂, probably because he locates concentrations of insects while making his territorial patrols. When the ♀ joins the ♂, he swoops close to her, which suggests close-range communication of some sort (possibly vocal). Ritualized interactions between the pair are conspicuous aspects of daily behaviour. There are at least three social vocalizations that are audible to humans; they are associated with aggression, mating and mother–young interactions (Wickler & Uhrig 1969).

During a study from mid-Dec to early Jul, courtship was observed in May and early Jun when rain was frequent and insects abundant (Vaughan & Vaughan 1986). Courtship includes brief (ca. 10 second) ‘aerial ballets’ during which the pair circle and chase each other, and longer displays during which the ♂ flies tight figure-eights close to his perching mate. Mating apparently occurs while the pair are hanging from a perch. The testes, which are unusually prominent and pendulous, have substantial deposits of melanin in the scrotal skin; as well as protecting developing spermatogonia from harmful ultraviolet radiation, this pigmentation may have a social/reproductive communication function (Kermott & Timms 1988). Parental behaviour has been described in detail by Vaughan & Vaughan (1987). The single young clings to its mother continuously until ca. one week before it first flies and forages. It grips a pubic nipple in the mouth, and holds the back of the mother’s neck with its feet. Periodically, it turns ‘upside down’ (i.e. head down) to suck. Older juveniles occasionally release their grip on the pubic nipple, turn ‘upside-down’, hold on by the feet only, and stretch, groom and flap their wings. Mothers lick the inguinal region of the young (perhaps to induce urination) and eat the faeces (perhaps to recycle water). Newly volant young forage with their parents and soon develop foraging strategies closely resembling those of the parents. They are weaned ca. 20 days after becoming volant. For at least 30 days more, they share the parents’ territory, synchronize grooming and foraging periods with those of the parents, and periodically huddle against the mother when roosting.

Monogamy, territoriality, division of labour, opportunistic foraging and long mother–young associations are probably adaptations to habitats with low carrying capacities and seasonal shortages of food (Vaughan & Vaughan 1986).

Reproduction and Population Structure Litter-size: one. Gestation ca. 3–3.5 months (Verschuren 1957, Anciaux de Faveaux 1972). Reproductive chronology uncertain. At 00° 36' N (near Kampi ya Samaki, Kenya), young were born in early Apr to all of five ♀♀ under observation, and courtship and attempted mating were observed in May and early Jun: no data from mid-Jul to early Dec (Vaughan & Vaughan 1986, 1987). These data suggest seasonal bimodal polyoestry (as in *C. cor*) but there are no data to confirm if or when other births occur in Kenya. In Sudan, a juvenile was recorded in Dec, and two ♀♀ with embryos 11.5 mm in Mar (Kock 1969a). At Faradje, NE DR Congo, Lang & Chapin (1917b) recorded ‘one large foetus in Mar and five young from Oct to Apr’ but these

data are inconclusive. In Garamba N. P., NE DR Congo, Verschuren (1957) recorded 4 of 4 ♀♀ pregnant in Mar, 1 of 1 near end of term in early Apr, and a juvenile in Apr, indicating births in early Apr with ♀♀ in synchrony: he found no evidence of births at other times of the year. Koopman *et al.* (1978) recorded that nine ♀♀ taken from Cella, Burkina in mid-Mar were pregnant; crown–rump lengths of embryos 13–33 mm, but they do not record if non-pregnant ♀♀ were caught at the same time, and there are no records for other months in Burkina. (These authors did not record pregnancies in May and Sep as stated by Nowak 1999.) In Tanzania, ♀♀ with well-developed embryos were recorded in late Jan, early Feb, early Apr and early Aug (Eisentraut 1958), and births have been reported during Jan, Apr, Aug and Nov (Anciaux de Faveaux 1972).

Predators, Parasites and Diseases Comparatively vulnerable to predation by diurnal birds of prey: they maintain constant vigilance and fly if approached by large birds. Captures by European Kestrels *Falco tinnunculus* have been observed (Vaughan & Vaughan 1986). One bat was found in the stomach of a Common Mamba *Dendroaspis angusticeps* (Allen & Lawrence 1936). Other predators include Bat Hawks *Macheiramphus alcinus*, and a Night Tree Viper *Boiga blandingii* (Wickler & Uhrig 1969 in Vohnhof & Kalcounis 1999). Ectoparasites include fleas *Echidnophaga aethiops* (Siphonaptera: Pulicidae), *Chiropteropsylla brockmani* (Siphonaptera: Ischnopsyllidae); a bat-fly *Raymondia planiceps* (Diptera: Streblidae); and mites *Ancystropus zebeborii* (Acari: Spinturnicidae), *Psorergatoides laviae* (Acari: Psorergatidae), *Lapidocarpus laviae*, *Olalidocarpus africanus*, *Alalidocarpus hilli*, *A. laviae* (Acari: Chirodiscidae), *Nycteriglyphus laviae* (Acari: Rosensteiniidae), *Rodhainyssus yunkeri* (Acari: Gastronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Family RHINOPOMATIDAE

MOUSE-TAILED BATS

Rhinopomatidae Bonaparte, 1838. Syn. Vert. Syst. In: Nuovi Ann. Sci. Nat., Bologna, 2: 111.

| | | |
|------------------------------|-------------------|--------|
| <i>Rhinopoma</i> (3 species) | Mouse-tailed Bats | p. 410 |
|------------------------------|-------------------|--------|

This is a monotypic family distributed from Africa (north of the Equator) to southern Asia through Arabia, the Middle East and India, mainly in semi-arid and arid habitats. There are currently four species (Van Cakenberghe & De Vree 1994, Simmons 2005) of which three occur in Africa and one in Arabia and the Middle East (*Rhinopoma muscatellum*). These bats of primitive structure are characterized by a tail that is exceptionally long and has at least half of its length projecting beyond the narrow interfemoral membrane (Figure 77), slit-like valvular nostrils that can be closed, and a small triangular noseleaf surmounting a hog-shaped muzzle (that gave the name to the genus) (see Figure 32e). Miller (1907) proposed the name Rhinopomidae and this was adopted by several authors; however, the original name is most commonly used. The family was reviewed by Hill (1977a) and more recently by Van Cakenberghe & De Vree (1994).

Rhinopomatids are small to medium-sized microbats with moderately long pelage that is generally more or less sepia grey (but varying in colour and tone across the geographic range), and usually paler ventrally. The face, rump and posterior portion of the abdomen are naked and medium brown. Sexes similar in colour, and ♂♂ are often slightly larger than ♀♀. A thickened narial pad is present on the end of the muzzle, surmounted by a distinct ridge-like dermal outgrowth (a rudimentary noseleaf). The ears are more or less triangular and joined across the forehead by a connecting band of skin; each ear has a simple but moderately long and erect tragus. Eyes are relatively large for a microbat. Wings rather narrow; second finger with two bony phalanges (cf. all other African families); all of the fingers are shorter, relative to the length of the forearm, than in any other bats (Figure 77). The tip of the wing can be shortened by folding to facilitate cursorial locomotion, but not to the same extent as in the Emballonuridae and Molossidae. This is achieved by the terminal phalanx of the third finger bending round, but not fully, upon the ventral surface of the wing (Rosevear 1965). The hindlimbs are moderately long; the toes (except the hallux) have three phalanges. The tail has sensitive hairs at its distal end. The skull is relatively short and broad; there are no postorbital processes: the skull of *Rhinopoma microphyllum* is illustrated as an example for the genus (Figure 77). Separate nasal swellings are present on each side of the rostrum. The sagittal crest is low and sharp. The auditory bullae are rather large. The premaxillae are separate from each other and from the adjacent part of the skull. The upper incisor (I^2) is very small, barely emerging from the gum. The canines are conical and simple. The first and second upper molars are lacking distinct hypocones. Dental formula $^{1113}/_{2123} = 28$.

Rhinopomatids roost in dry caves, crevices, various underground structures and buildings including tombs and pyramids; their day-roosts are impregnated with a characteristic smell. An oily substance is secreted by the numerous glands of the facial region in response to stimuli (e.g. touch, fear, aggression) (Kulzer *et al.* 1985). Sometimes, they share day-roosts with other species of bats, including other

Figure 77. Characters of African bats in the family Rhinopomatidae. Flight membranes and bones of wing, hindlimb and tail (e.g. *Rhinopoma hardwickii*). Skull (e.g. *R. microphyllum*; BMNH 3.12.8.26)

species of rhinopomatids, but the different species do not roost in exactly the same places. Rhinopomatids sometimes roost in clusters numbering up to many thousands of individuals, but most of the groups are smaller (10–100 bats). The sexes segregate for at least part of the year. Little is known of their breeding habits in Africa.

These insect-eating bats are poor fliers and tire quickly. Their wings are adapted for fast flight in open areas, gliding or rapid wing-flapping. When echolocating, ultrasound pulses are emitted through the mouth; the echolocation calls are loud with little modulation of frequency when the bats are foraging (Figures 82 and 83), and become more frequency-modulated when the bats are approaching prey or when they are emerging from their day-roosts in groups (Schmidt & Joermann 1986). Rhinopomatids can accumulate fat in the lower abdominal region; this is metabolized when food is scarce. These bats do not hibernate, but they can remain torpid for several days. Their water metabolism reflects extreme adaptations to desert habitats; the concentration of urea in the blood is high, and the skin is poorly vascularized so that loss of water through evaporation is minimal, even

at high temperatures. Some populations are suspected to migrate.

No fossils referable to this family have been found; the oldest remains of rhinopomatids were collected from Egyptian tombs, which have been inhabited by these bats for ca. 3000 years.

All of the three species of rhinopomatids in Africa occur in the tropics; two also extend northwards into temperate habitats. In Africa, one species is found in semi-desert vegetation zones, and the other two are found in both desert and semi-desert vegetation zones. Two species have also been found in montane habitats (but not above ca. 1200 m).

Based on morphological data, the family Rhinopomatidae was placed in the superfamily Rhinopomatoidea by Simmons (1998) and Simmons & Geisler (1998), but more recent molecular studies have contradicted many groupings based on morphological data and, pending resolution of the controversies, Simmons (2005) does not recognize the chiropteran superfamilies.

All rhinopomatids belong to the genus *Rhinopoma*.

Stéphane Aulagnier

GENUS *Rhinopoma* Mouse-tailed Bats

Rhinopoma E. Geoffroy, 1818. Description de l’Egypte 2: 113. Type species: *Vespertilio microphyllus* Brünnich, 1782.

This genus contains four species of which three occur in Africa. As this is the only genus in the family Rhinopomatidae, its characters are given in the family profile.

Almost all authors recognize two main species that are widely distributed in Africa and Asia: the comparatively large *Rhinopoma microphyllum* and the smaller *R. hardwickii* (original spelling). Additionally, most authors agree to recognize a third species, smaller than the former ones – this is *R. muscatellum*, an extralimital species currently considered to occur from Arabia to SW India (Simmons 2005). Subsequently, based on a biometric study of 15 skull and 14 external measurements, and six morphological characters, Van Cakenberghe & De Vree (1994) confirmed the validity of *R. muscatellum* and, in addition, proposed specific status for *macinnesi*, a taxon first described from Kenya as a subspecies of *R. cystops* by Hayman (1937) and later considered a subspecies of *R. hardwickii* by Kock (1969a) and Hill (1977a). Small rhinopomatids have also been collected in Eritrea since Senna (1905). Lagen *et al.* (1974) and Demeter & Topal (1982) suspected that these represented *R. muscatellum*, but Van Cakenberghe & De Vree (1994) indicated that they represent *R. macinnesi*.

The three species that occur in Africa can be distinguished by their distributions and/or the combination of characters given in Table 16. These characters are as follows:

Forearm length (FA).

Greatest length of skull (GLS).

Relative length of tail. Expressed as percentage of FA.

Rostrum shape. The shape of the rostrum, viewed dorsally, can be triangular or pentagonal (Figure 78).

Figure 78. Variations in the outline of the rostrum (viewed dorsally) in African *Rhinopoma* (following Van Cakenberghe & De Vree 1994). (a) Rostrum of *Rhinopoma macinnesi* showing triangular outline. (b) Rostrum of *Rhinopoma microphyllum* showing pentagonal outline.

Sagittal crest. Can be inconspicuous and sometimes absent, or prominent.

ABOVE: Figure 79. Variations in the extent of development of the nasal swellings in African *Rhinopoma* (following Van Cakenberghe & De Vree 1994). (a) Weakly developed (e.g. *R. microphyllum*). (b) Moderately developed (e.g. *R. macinnesi*).

RIGHT: Figure 80. Variations in the shape of the posterior palatal emargination, and the extent to which it reaches forward, in African *Rhinopoma* (following Van Cakenberghe & De Vree 1994). (a) U-shaped and reaching as far forward as the line connecting the posterior edges of the third molars (e.g. *R. macinnesi*). (b) V-shaped and not reaching as far forward as the line connecting the posterior edges of the third molars (e.g. *R. microphyllum*).

Development of nasal swellings. Said to be weak for the genus if the most anterior point of the nasal bones (viewed laterally) is posterior to the upper canines (Figure 79a), moderate if the most anterior point is directly above the canines (Figure 79b), or strong if the most anterior point is anterior to the canines. The development is strong only in the extralimital species, *R. muscatellum*.

Another character, mentioned only in the species profiles is:

Posterior palatal emargination. Can be U-shaped or V-shaped, and can reach, or not reach, as far forward as the line connecting the posterior edges of the third molars (M^3 – M^3) (Figure 80).

Stéphane Aulagnier

Table 16. Key to the African species of *Rhinopoma*. For explanation of the characters, see Genus *Rhinopoma*. Measurements and distributions pertain only to Africa.

| Distribution | FA (mm) | GLS (mm) | T % of FA | Rostrum outline; sagittal crest; nasal swellings | Species |
|--|--------------|------------------|---------------|---|------------------------|

Inconspicuous
Usually weakly developed | <i>R. hardwickii</i> |
| Widespread north of Equator in Mediterranean Coastal, Sahara Arid, Sahel Savanna and Sudan Savanna BZs | 68.6 (62–74) | 20.4 (18.7–21.5) | 92 (73–126) | Pentagonal
Very prominent
Weakly developed | <i>R. microphyllum</i> |

***Rhinopoma hardwickii* LESSER MOUSE-TAILED BAT**

Fr. Petit rhinopome; Ger. Hardwickses Mausschwanz-Fledermaus

Rhinopoma hardwickii Gray, 1831. Zool. Misc. 1: 37. India, restricted to Bengal by Qumsiyeh *et al.* (1992).

Taxonomy Originally *Rhinopoma hardwickii*. Thomas (1903a) changed the name to *hardwickei* because the species was named after Major-General Hardwicke and subsequently both names have been used. Synonyms (excluding misspellings; African only): *arabium*, *brevicauda*, *brevicaudatum*, *cystops*, *ferox*, *longicaudatum*, *microphyllus* E. Geoffroy Saint-Hilaire, 1818, *sennaariense*, *sondaicum*. Subspecies: four; two in Africa. Chromosome number (Palestine): $2n = 36$; $aFN = 68$ (Qumsiyeh & Baker 1985). Since this profile was submitted, *cystops* has been restored to specific status by Hulva *et al.* (2007).

Description Small microbat with rudimentary 'noseleaf' and extremely long, mostly free tail; medium-sized for an African *Rhinopoma* (FA: 50–62 mm); tail considerably longer than FA; 'noseleaf' comparatively large; nasal swellings only sometimes reaching as far forward as upper canines. Sexes similar in colour; ♂♂ on average slightly larger than ♀♀. Pelage fine; mid-dorsal hairs 7–8 mm; rump and lower abdomen naked or only sparsely haired; face and ears naked. Dorsal pelage sepia grey; hairs with paler base, especially on the flanks. Ventral pelage paler and greyer, sometimes very pale to white posteriorly. Muzzle upturned; nostrils valvular; dermal ridge ('noseleaf') relatively large; upper margin triangular in ca. 75% of cases, or with a central papilla. Ears subtriangular, joined across forehead by connecting band of naked skin. Tragus sickle-shaped, conspicuous, erect, narrow, moderately long (just < half of ear length); tip bluntly rounded, usually with small, finger-like projection rising from anterior edge, which gives the tip a notched appearance (Figure 81a). Eyes large for a microbat. Wings and interfemoral membrane medium brown, naked, attaching to each tibia well above the ankle (at ca. two-thirds to three-quarters of distance from knee). Interfemoral membrane very narrow. Hindfeet comparatively small and delicate. Tail very slender, projecting well beyond interfemoral membrane, usually longer than forearm (118 [87–155]% of FA, $n = 338$; Van Cakenberghe & De Vree 1994).

Skull medium-sized for a *Rhinopoma*. Sagittal crest present but not conspicuous anteriorly, absent posteriorly; lambdoid crest well developed ventrally, absent dorsally. Rostrum (viewed dorsally) is triangular and relatively large. Nasal swellings usually weakly developed for the genus (the most anterior points of the nasal bones are usually posterior to the canines [as in *R. macinnesi*, Figure 79b], but are

sometimes level with them) (Figure 79). Posterior palatal emargination U-shaped, usually extending forward as far as the line connecting the posterior edges of the third molars (as in *R. macinnesi*, Figure 80a).

Geographic Variation Two subspecies occur in Africa (Hill 1977a, Van Cakenberghe & De Vree 1994):

R. h. cystops: central part of African geographic range (S Algeria, S Egypt, N Niger). On average smaller (FA: 53.0 [50–57] mm; GLS: 16.2 [15.4–16.7] mm, $n = 22$). Recently restored to specific status by Hulva *et al.* (2007).

R. h. arabium: remainder of African geographic range and, extraliminally, Arabia. On average larger (FA: 57.7 [53–62] mm; GLS: 17.2 [16.3–18.0] mm, $n = 38$).

Similar Species Only two other species of African bats have an extremely long tail protruding far beyond the interfemoral membrane:

Rhinopoma macinnesi. Often smaller (FA: 48.6 [45–53] mm; GLS: 15.4 [14.2–16.2] mm). Eritrea, Ethiopia, Somalia and N Kenya.

R. microphyllum. Larger (FA: 62–74 mm; GLS: 18.7–21.5 mm). Tail usually shorter than forearm.

Distribution In Africa, mainly recorded around the periphery of the Sahara Arid BZ, in arid inland parts of the Mediterranean Coastal BZ and in the Sahel Savanna, Sudan Savanna and Somalia–Masai Bushland BZs, but also found in mountainous areas of the Sahara and in the Afromontane–Afroalpine BZ in Ethiopia. Recorded from

Figure 81. Variations in the shape of the tragus of (a) *Rhinopoma hardwickii* and (b) *Rhinopoma microphyllum*: left tragus illustrated; both drawn to same length.

Rhinopoma hardwickii

Morocco, Algeria (Saharan Atlas and Hoggar), Tunisia, Libya, Egypt and southwards to Mauritania, Senegal (locality not mapped), Mali, Burkina, Niger, N Nigeria, Chad (Tibesti), Sudan, Eritrea, Djibouti, Ethiopia, N Somalia (Hill 1977a, Van Cakenberghe & De Vree 1994, Benda *et al.* 2004a). The known specimens from Kenya refer to *R. macinnesi* according to Van Cakenberghe & De Vree (1994). Extraliminally: through Arabia to India, Myanmar and Sunda Is.

Habitat Inhabits arid and semi-desert vegetation zones where suitable day-roosts and food are available; penetrates the wooded steppe in some eastern areas. Absent from areas of high humidity. Ranges from sea level in Egypt to ca. 1100 m in Morocco and Algeria (Aulagnier & Destre 1985, Kowalski & Rzebik-Kowalska 1991). Recorded from bank of large river flanked by riverine forest and on slope of a dormant volcano in Awash N. P., Ethiopia, a region of semi-desert grassland with areas of *Acacia* scrub (Largen *et al.* 1974); along the Nile R. in Egypt (Gaisler *et al.* 1972); in an oasis with gardens and orchards surrounded by sandy desert and hamada in Libya (Benda *et al.* 2004a); and in gorges of wadis with some *Tamarix* *Tamarix* sp. and Oleanders *Nerium oleander* in Morocco (Aulagnier & Destre 1985).

Abundance Uncertain. More widely distributed and more often recorded than *R. microphyllum*. Seems to be particularly abundant near oases. However, both distribution and abundance are indubitably insufficiently investigated because the roosts and suitable habitats are very often unreachable.

Adaptations Aspect ratio low; wing-loading high; wing-tip extremely short: the short wings and absence of an interfemoral membrane contribute to the high wing-loading (Norberg & Rayner 1987). Flight fast and very distinctive – characterized by a series of alternating flutters and glides, and a rising and falling motion (Harrison & Bates 1991). This undulating pattern helps to save energy expended during flight (Rayner 1985). Cannot hover (Habersetzer 1986 in Norberg & Rayner 1987). Climbs and scuttles with agility; tail often held at stiff right-angle to body during these activities. Roosts by day in warm caves, underground tunnels, wells, ruins, catacombs, mosques and deserted buildings. Clings to ceilings (less often to walls), with tail

extended and limbs wide apart. When disturbed, escapes by climbing with agility (rather than by flying), with the tail often held at a stiff right-angle to body. Roost temperatures range from 21 to 34.5 °C and relative humidities can be as low as 35% (Kock 1969a, Gaisler *et al.* 1972) or even 20–25% (Poulet 1970). Surprisingly tolerant of light; in summer, sometimes roosts in fissures, small crevices and among boulders that are fully exposed to strong solar radiation (Kowalski & Rzebik-Kowalska 1991); also roosts in total darkness (Poulet 1970, Gaisler *et al.* 1972). Moves to underground day-roosts in winter. Stays active throughout most of winter but sometimes has periods of extended rest when it survives on accumulated deposits of fat (Kock 1969a, Poulet 1970, Vogel 1977, Aulagnier & Destre 1985, Kowalski & Rzebik-Kowalska 1991). Often roosts with *Asellia tridens*, *Rhinolophus blasii*, *R. clivus*, *R. ferrumequinum*, *R. hipposideros*, *Plecotus* spp. and *Miniopterus schreibersii* in the north of its African geographic range (Gaisler *et al.* 1982, Aulagnier & Destre 1985); and with *Rhinopoma microphyllum*, *Asellia tridens*, *Taphozous perforatus*, *Nycteris thebaica* and *Hipposideros ruber* in the south (Kock 1969a, Poulet 1970, Koch-Weser 1984). For more information, see Qumsiyeh & Jones 1986.

Foraging and Food Forages by slow-hawking. Emerges from day-roost early after sunset. Foraging sites in Africa not known: flies 10–15 m above ground when commuting to foraging sites. In India, usually forages in open spaces (above and around canopies and over clearings) ca. 6–9 m above ground (Neuweiler 1984); on bright moonlit nights foraging is suppressed and takes place under cover of canopies (Usman 1989). In Israel, feeds mainly on Coleoptera and Hymenoptera, but also on Homoptera and Heteroptera (Whitaker & Yom-Tov 2002).

Echolocation The echolocation of *Rhinopoma* spp. is considered acoustically primitive by Simmons (1979) because these bats use signals with four or more harmonics (usually with maximum energy in second harmonic) and little frequency modulation. Search-phase call-shape (India) usually CF but calls sometimes begin with a very narrow-bandwidth descending FM-component (Figure 82; Habersetzer 1981). CF-frequency (second harmonic) during pursuit of insects (Egypt) 36–40 kHz; call-duration 6–10 ms; call repetition-

Figure 82. Echolocation calls of *Rhinopoma hardwickii*. (a) Sonogram of a sequence of search-phase calls: one bat flying in open prior to returning to its roost. (b) Calls emitted as this bat approached its roost (based on Habersetzer 1981). Only the dominant harmonic (second) is shown (for harmonics, see Habersetzer 1981). Note that the time-scale relative to the frequency scale is substantially different to that of most other sonograms in other profiles.

rate ca. 10 calls/sec. Darting flight is accompanied by shortening the signals to 1 ms or less and increasing the call repetition-rate to ca. 100 calls/sec; laboratory tests indicated that Doppler shift compensation is probably not used by this species (Simmons *et al.* 1984). When three individuals flew together in the laboratory, each used a different CF-frequency, suggesting that they regulated the CF-frequency to avoid jamming each other (Habersetzer 1981). After landing, CF calls of mean duration 74 ms are emitted and these have maximum energy in the fundamental harmonic; the purpose of these calls (echolocation and/or communication) is not known (Habersetzer 1981). The first harmonic frequencies (18–20 kHz; Simmons *et al.* 1984) of calls made in a roost in Morocco were audible to humans (Aulagnier & Destre 1985).

Social and Reproductive Behaviour Roosts singly or in groups ranging in size from a few individuals to several hundred (Poulet 1970, Gaisler *et al.* 1972). Group-members cling apart (i.e. without touching their neighbours). Facultative sexual segregation only occurs during summer (Panouse 1951, Kock 1969a, Poulet 1970).

Reproduction and Population Structure Litter-size: one. In India, absence of young from Oct to Apr, and sightings of neonates mainly in Jun, indicate that the reproductive chronology is restricted seasonal monoestry (Brosset 1962) with copulation from mid-Feb to early Mar; gestation 95–100 days; lactation for ca. two months (Bates & Harrison 1997). In Egypt, 27 of 30 adult ♀♀ were pregnant and all adult ♂♂ were sexually inactive in Apr; no data for other months (Gaisler *et al.* 1972), and in Sudan, early stages of pregnancy were recorded in late Mar (Kock 1969a); so births were expected from May to early Jun at these localities. In Israel, non-volant young were caught in late May and two ♀♀ were still pregnant at this time (Yom-Tov *et al.* 1992). In Burkina, ♀♀ carried half-grown young in the wet season (mid-Jul) (Koch-Weser 1984). These data are consistent with restricted seasonal monoestry.

Predators, Parasites and Diseases Ectoparasites in Africa include fleas *Chiropteropsylla aegyptia* (Siphonaptera: Ischnopsyllidae), *Xenopsylla ramesis* (Siphonaptera: Pulicidae); bat-flies *Phthiridium integrum*, *Eycampsipoda hyrtlui* (Diptera: Nycteribiidae), *Ascodipteron rhinopomatos*, *Brachytarsina diversa* (Diptera: Streblidae); and ticks *Argas transgaripepinus*, *Carios vespertilionis*, *C. boueti* (Acari: Argasidae) (Hastriter & Tipton 1975, Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Rhinopoma macinnesi MACINNES'S MOUSE-TAILED BAT

Fr. Rhinopome de MacInnes; Ger. MacInnes' Mausschwanz-Fledermaus

Rhinopoma macinnesi Hayman, 1937. Ann. Mag. Nat. Hist., ser. 10, 19: 530. Bat I., near Central I., L. Rudolf [= L. Turkana], Kenya.

Taxonomy Originally *Rhinopoma cystops macinnesi*. Synonyms: none. Considered a subspecies of *R. hardwickii* by some authors (e.g. Kock 1969a, Koopman 1975, Hill 1977a, Aggundey & Schlitter 1984) and of *R. muscatellum* (a small Arabian species) by Largent *et al.* (1974), but considered to be a distinct species by Van Cakenberghe & De Vree (1994). Chromosome number: not known.

Description Small microbat with rudimentary 'noseleaf' and extremely long, mostly free tail; the smallest African *Rhinopoma* (FA: 45–53 mm); tail considerably longer than FA; nasal swellings reaching forward to level of upper canines. Sexual dimorphism: no information. Pelage fine; rump and lower abdomen naked or sparsely haired; mid-dorsal hairs ca. 7 mm. Dorsal pelage sepia grey. Ventral pelage essentially grey. Muzzle upturned; nostrils valvular, dermal ridge ('noseleaf') relatively large. Ears subtriangular, joined across forehead by connecting band of skin. Tragus: no information. Eyes

large for a microbat. Wings and interfemoral membrane medium brown, naked. Interfemoral membrane very narrow. Hindfeet comparatively small and delicate. Tail very slender, projecting well beyond interfemoral membrane, longer than forearm (136 [122–158]% of FA, n = 40; Van Cakenberghe & De Vree 1994).

Skull small for a *Rhinopoma*. Sagittal crest reduced (not conspicuous) or absent. Rostrum (viewed dorsally) is triangular. Nasal swellings moderately developed for this genus (the anterior-most points of the nasal bones are level with the upper canines) (Figure 79b). Posterior palatal emargination U-shaped; extending forward as far as the line connecting the posterior edges of the third molars (Figure 80a).

Geographic Variation None recorded.

Similar Species Only two other species of African bats have an extremely long tail protruding far beyond the interfemoral membrane:

Rhinopoma hardwickii. Often larger (FA: 56.0 [50–62] mm; GLS: 16.8 [15.4–18.0] mm). Widespread.

R. microphyllum. Larger (FA: 62–74 mm; GLS: 18.7–21.5 mm). Tail usually shorter than FA. The most anterior points of the nasal bones are posterior to the canines.

Distribution Endemic to Africa. As yet known only from the Somalia–Masai Bushland BZ. Recorded from Abbas on the S Eritrean coast; Galago Oasis in Somalia; and from Central I. and Bat I. in L. Turkana, Lesucut I. and Gibralter I. in L. Baringo, Kampi ya Samaki near L. Baringo, and Lodwar, in Kenya (Hayman 1937, Aggundey & Schlitter 1984, Van Cakenberghe & De Vree 1994). A specimen from Lokomarinyang in extreme SE Sudan (Koopman 1975) is no longer assigned to this species (Van Cakenberghe & De Vree 1994).

Habitat The known localities are in semi-desert vegetation zones including semi-desert grassland and shrubland, and *Acacia–Commiphora* deciduous bushland and thicket (terminology: White 1983). Ranges from sea level in Eritrea to ca. 500 m in Kenya. Three of the four Kenyan records are from islands in large lakes.

Abundance Probably a rare species as no specimens were collected during several expeditions into its geographic range.

Remarks Very little is known about the habits of this species. Climbs and scuttles with some agility; tail often held at stiff right-angle to body during these activities (Kingdon 1974 as *R. hardwickii*). Moves backwards into crevices with its tail waving in all directions; tip of tail has very fine hairs and these, and the tail itself, possibly have a sensory role (Kingdon 1974).

Conservation IUCN Category: Data Deficient.

Population very restricted in its area of occupancy – occurs in a small region of Kenya and only two other localities are known.

Rhinopoma microphyllum GREATER MOUSE-TAILED BAT

Fr. Grand rhinopome; Ger. Ägyptische Mausschwanz-Fledermaus

Rhinopoma microphyllum (Brünnich, 1782). Dyrenes Historie 1: 50. Giza, Egypt.

Taxonomy Originally *Vespertilio microphyllus*. Synonyms in Africa: *cordofanicum*, *lepsianum* and *tropicalis* (extralimitally, five others listed by Simmons [2005]). Subspecies: four; one in Africa (but see Geographic Variation). Chromosome number (Palestine): 2n = 42; aFN = 66 (Qumsiyeh & Baker 1985).

Description Medium-size microbat with rudimentary ‘noseleaf’ and very long, mostly free tail; the largest *Rhinopoma* in Africa (FA: 62–74 mm); tail usually shorter than FA; ‘noseleaf’ comparatively small; nasal swellings not reaching as far forward as the canines. Sexes similar. Pelage fine, silky; mid-dorsal hairs 5–7 mm; rump and

lower abdomen, face, ears and throat naked or almost so. Dorsal pelage greyish-brown, sometimes paler; hairs unicoloured. Ventral pelage paler to whitish. Muzzle upturned; nostrils valvular; dermal ridge (‘noseleaf’) relatively small with upper margin variable in shape. Ears subtriangular, joined across forehead by band of skin. Tragus sickle-shaped with small basal lobule; tip bluntly rounded, sometimes smooth, sometimes with projection from anterior margin giving the tip a notched appearance. Eyes large for a microbat. Wings and interfemoral membrane medium brown, naked; second finger with two phalanges. Hindfeet slender but, on average, longer than those of *R. hardwickii*. Interfemoral membrane very narrow. Wing

and interfemoral membranes attaching to each tibia well above the ankle (at ca. three-quarters of distance from knee). Tail very slender, projecting well beyond interfemoral membrane but usually shorter than forearm (92 [73–126]% of FA, $n = 139$; Van Cakenberghe & De Vree 1994) and usually shorter than HB.

Skull (Figure 77) large and robust for a *Rhinopoma*. Sagittal crest very prominent anteriorly and posteriorly; lambdoid crest comparatively well developed dorsally and ventrally. Rostrum (viewed dorsally) is pentagonal (Figure 78b) and relatively small. Nasal swellings weakly developed for the genus (the most anterior points of the nasal bones are posterior to the canines) (Figure 79a). Posterior palatal emargination sharply V-shaped and not extending as far forward as the line connecting the posterior edges of the third molars (Figure 80b). Complete cranial and postcranial osteology in Sinha (1982).

Geographic Variation Specimens from some areas (e.g. S Sudan and Wase Rock, Nigeria) are possibly larger on average than those from elsewhere in Africa and, based on this, Kock (1969a) and Hill (1977a) recognized two subspecies in Africa, *R. m. tropicalis* and *R. m. microphyllum*. However, the differences are not considered to justify the subspecific status of *tropicalis* by Van Cakenberghe & De Vree (1994).

Similar Species Only two other species of African bats have an extremely long tail protruding far beyond the interfemoral membrane:

Rhinopoma hardwickii. Smaller (FA: 50–62 mm; GLS: 15.4–18.0 mm).

Tail almost always longer than FA.

R. macinnesi. Smaller (FA: 45–53 mm; GLS: 14.2–16.2 mm). Tail longer than FA. Most anterior points of nasal bones are level with the canines.

Distribution In Africa, mainly recorded in the arid regions of the Mediterranean Coastal BZ, the north-western and eastern regions

of the Sahara Arid BZ and the Sahel Savanna BZ, and marginally in the Sudan Savanna, Somalia–Masai Bushland and Afromontane–Afroalpine BZs. Possibly also occurs in scattered localities in the central Sahara Arid BZ. Recorded from SE Morocco, W Mauritania, Senegal, Burkina, Nigeria, N Cameroon, Sudan, Djibouti and Egypt (Kock 1969a, Qumsiyeh 1985, Aulagnier & Thévenot 1986, Le Berre 1990, Van Cakenberghe & De Vree 1994, Pearch *et al.* 2001, Benda *et al.* 2004d). Extraliminally: Arabia and Middle East to India and Sumatra.

Habitat Inhabits arid regions (rainfall <300 mm) with very sparse vegetation, ranging from sea level in Egypt (Qumsiyeh 1985) to ca. 1200 m in Morocco (Aulagnier & Destre 1985). Also exploits semi-arid habitats (rainfall 400–500 mm) in the southern part of the geographic range.

Abundance Uncertain; likely to be populations in regions not yet investigated, and known populations have not been adequately surveyed. Colonies of several thousands have been reported in Egypt and Mauritania (see Social and Reproductive Behaviour).

Adaptations Aspect ratio medium-high; wing-loading very high; wing-tip extremely short (Norberg & Rayner 1987). Flight fast; alternates fluttering with gliding so flight-path is undulating, as in *R. hardwickii* (Roberts 1977 in Norberg & Rayner 1987). Climbs and scuttles with agility. Roosts by day in more-or-less dark crevices, small caves, mines, underground tunnels, wells, old monuments and buildings; tolerates low relative humidities (20–25%) and light. Clings to ceilings and walls with its limbs spread out and the sensory tail looking like a fifth limb. If disturbed, climbs with agility across vertical cliffs instead of hiding in deep crevices (Aulagnier & Destre 1985). Sometimes shares day-roosts with *Taphozous perforatus*, but the roost-sites of each species are always far apart. At Khartoum, Sudan, found roosting in a cave shared with a colony of *Asellia tridens* (Happold 1967). In Mauritania and Burkina, commonly roosts with *R. hardwickii*, often in larger numbers (Poulet 1970, Koch-Weser 1984). In India, migrates on a seasonal basis (Gopalakrishna 1986). In Mauritania, by the end of autumn or the wet season, considerable amounts of fat are deposited in the thighs, the lower portion of the abdomen and the upper part of the interfemoral membrane, and used later as a source of energy (Poulet 1970). In Africa, remains active throughout the year. Adaptations to desert habitats include skin that is less vascularized and produces very little perspiration even when temperatures are high, and the ability to tolerate concentrations of urea in the blood that are 4–5 times higher than in humans (see Schlitter & Qumsiyeh 1996).

Foraging and Food Forages by slow-hawking. Foraging areas not known. In Mauritania in autumn, reported to forage for a comparatively short period (1–1.5 h); stomachs of three individuals contained mainly Coleoptera (Tenebrionidae, Scarabaeidae, Cucurionidae) and some Hemiptera (Poulet 1970). In Israel, feeds mainly on Coleoptera (80% of volume), and also on Lepidoptera, Hymenoptera and Homoptera (Whitaker & Yom-Tov 2002).

Echolocation Search-phase call-shape (Egyptian animals in laboratory) CF (multiharmonic) (see Figure 83; Schmidt & Joermann

1983). CF-frequency (second harmonic) 27–31 kHz (but each individual emits only one frequency); call-duration ‘long’. When flying in a flight-tunnel, this species emits shorter and slightly frequency-modulated calls (as does *R. hardwickii*). However, if three individuals fly together in the flight-tunnel, instead of avoiding jamming by changing to three different frequencies (see *R. hardwickii*), the main response of these bats is to greatly increase the intensity of their calls (Schmidt & Joermann 1983).

Social and Reproductive Behaviour Usually roosts in groups varying in size from a few individuals in crevices to colonies of several thousands in Egyptian monuments and underground sites in Mauritania (4000–5000 of both species of *Rhinopoma* were recorded in several wells near Akjoujt by Poulet 1970). Even in very large colonies, individuals never roost close to each other (Poulet 1970). The sexes segregate during part of the year but this is not related to parturition (at one roost in Morocco, only ♂♂ were present in Dec; both sexes were present in Jun; Heim de Balsac 1948).

Reproduction and Population Structure Litter-size: one. In India, the reproductive chronology is restricted seasonal monoestry (Brosset 1962), with spermatogenesis in winter (testes reach maximum size by late Jan), copulation around Mar; births in second half of Jun or early Jul; young weaned in Aug to early Sep after lactation period of four weeks (see Schlitter & Qumsiyeh 1996). Both sexes reach sexual maturity in 18–19 months (Schlitter & Qumsiyeh 1996).

Predators, Parasites and Diseases Occasionally preyed on by Pharaoh Eagle-owls *Bubo ascalaphus* (Aulagnier 1989, Aulagnier & Denys 2000). Ectoparasites (in Egypt) include fleas *Ischnopsylla consimilis*, *Chiropteropsylla aegyptia* (Siphonaptera: Ischnopsyllidae); bat-flies *Ascodipteron namrui*, *Brachytarsina africana*, *B. diversa*, *B. kollari* (Diptera: Streblidae); ticks *Carios vespertilionis*, *C. boueti*, *Alectorobius tholozani* (Acari: Argasidae); and mites *Meristaspis lateralis* (Acari: Spinturnicidae) and *Liponyssus lepidopeltis* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Conservation should include monitoring of human disturbance of major roosts.

Family EMBALLONURIDAE
SHEATH-TAILED BATS

Emballonuridae Gervais, 1855. In: F. Comte de Castelnau, Exped. Partes Cen. Am. Sud., Zool. (Sec. 7), Vol. 1, pt 2 (Mammifères), p. 62 footnote.

| | | |
|---------------------------------|--------------------|--------|
| Subfamily Emballonurinae | | p. 421 |
| <i>Coleura</i> (1 species) | Sheath-tailed Bats | p. 421 |
| Subfamily Taphozoinae | | p. 424 |
| <i>Saccolaimus</i> (1 species) | Pouched Bats | p. 424 |
| <i>Taphozous</i> (5 species) | Tomb Bats | p. 427 |

This is a polytypic family that is distributed widely in the tropical and sub-tropical regions of the world. There are 13 extant genera (of which four are monotypic) and 51 extant species, but only three genera and seven species occur in Africa (Simmons 2005). Emballonurids have short sleek pelage, a relatively long body, a triangular head with pointed muzzle, moderately large ears, small but conspicuous eyes, no noseleaf, long narrow wings and a unique tail that projects upwards through the centre of the interfemoral membrane into a sheath of skin (Figure 84e and f). None are considered to be pests.

African emballonurids range in size from small to very large (FA: 44–95 mm). *Saccolaimus peli*, the largest emballonurid in Africa, is the third largest insectivorous bat in Africa (FA: 87–95 mm). Males and ♀♀ are usually similar in size and colour. The pelage is short and sleek and does not extend onto the flight-membranes; the posterior of the body is naked in some species. The body is elongated and moderately robust. The head is slightly flattened, the cranial area is broad and the muzzle is conical. The lacrimal region is not swollen. The forehead is either slightly concave or there is a deep depression between the eyes. The nostrils are close together. The upper lip has a small bare patch below the nostrils; this is matched by a larger prominence on the lower lip, which is divided by a vertical groove in some genera. During echolocation, the lips open slightly and the prominences on the lips form a small O through which the sound is emitted. The ears are relatively short (ca. 26–33% of FA), widely separated, roughly triangular with rounded tips; they point backwards and lie flat against the head and neck when these bats rest. The outer margin has a large

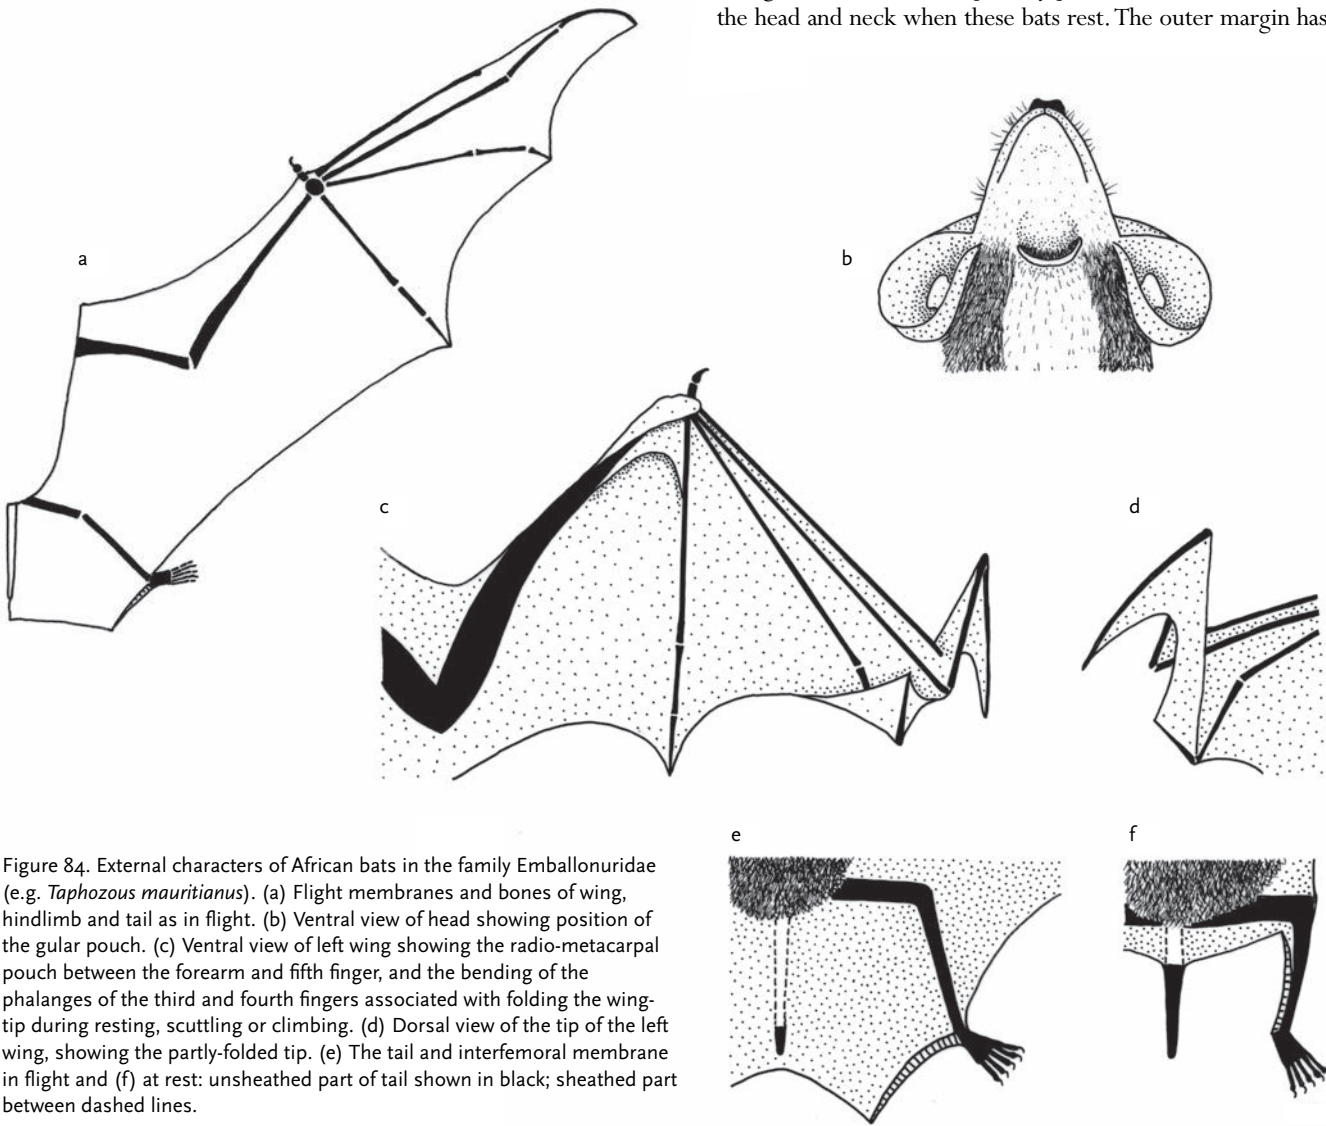

Figure 84. External characters of African bats in the family Emballonuridae (e.g. *Taphozous mauritanus*). (a) Flight membranes and bones of wing, hindlimb and tail as in flight. (b) Ventral view of head showing position of the gular pouch. (c) Ventral view of left wing showing the radio-metacarpal pouch between the forearm and fifth finger, and the bending of the phalanges of the third and fourth fingers associated with folding the wing-tip during resting, scuttling or climbing. (d) Dorsal view of the tip of the left wing, showing the partly-folded tip. (e) The tail and interfemoral membrane in flight and (f) at rest: unsheathed part of tail shown in black; sheathed part between dashed lines.

Figure 85. Variations in the shape of the tragus of some African Emballonuridae. (a) *Coleura afra*. (b) *Saccolaimus peli*. (c) *Taphozous hildegardeae*. (d) *T. mauritanus*. (e) *T. nudiventris*. (f) *T. perforatus*. Left tragus illustrated; all drawn to same length.

antitragus, which extends forwards almost to the mouth; the tragus is conspicuous and its shape is a means of distinguishing the African genera (Figure 85). The eyes are large for a microbat and, during the day, emballonurids watch for danger and sometimes fly away, without echolocating, if they are disturbed. In some species, there is a glandular region on the throat, which may range from a patch of bare skin (gular patch) to a deep pouch (gular pouch or sac) (Figure 84b). Gular patches and pouches are sometimes less developed, or absent, in ♀♀. Pelage in the gular area of the throat is sometimes black and referred to as a 'beard'. The wings are long and narrow; the second finger has a long metacarpal but no bony phalanges. In most species, a small flap of skin stretches between the forearm and the metacarpal of the fifth finger: this is the radio-metacarpal pouch and its function is not known. Except during flight, the tip of each wing folds back above the remainder of the wing in a way unique to this family: the first phalanx of the third finger folds upwards and backwards to lie against the metacarpal while the second phalanx folds downwards to lie against the first (Figure 84c and d). This shortens the wings and allows the membranes to be 'furled' tightly against the forearm. At the same time, the tail projects into its sheath allowing the elastic interfemoral membrane to contract and lie close against the body. These adaptations enable emballonurids to scuttle and climb very rapidly over horizontal and vertical surfaces without being impeded by the flight-membranes. The interfemoral membrane is supported by substantial calcars (Figure 84e and f). During flight, the hindlimbs and calcars can stretch outwards and backwards thereby increasing the area of the interfemoral membrane and causing the terminal half of the tail to slide into it. It is probable that the area and curvature of the interfemoral membrane is frequently adjusted during flight. The hindlimbs are moderately short; the toes (except hallux) have three phalanges. The tail is relatively short (21–26% of TL in African emballonurids). There are no pubic nipples.

The skull has long, slender postorbital processes, which curve outwards and downwards behind each orbit (Figure 86). These processes do not fuse with the supraorbital ridges to form a concave frontal plate (cf. Nycteridae and Megadermatidae), and no other microbats have postorbital processes. The profile of the forehead

Figure 86. Craniodental characters of African bats in the family Emballonuridae. (a) Lateral view of skull showing strongly concave profile of forehead region (e.g. *Taphozous perforatus*, BMNH 3.12.8.24). (b) Lateral view of skull showing weakly concave profile of forehead region (e.g. *Taphozous nudiventris*, ZFMK 96.548). (c) Dorsal view of skull (e.g. *T. perforatus*). (d) Ventral view of skull (e.g. *T. perforatus*).

region (viewed laterally) can be strongly concave (Figure 86a) or very weakly concave (sometimes almost straight to very slightly convex) (Figure 86b). Supraorbital ridges are present. The sagittal crest is usually low but sometimes well developed. An occipital helmet is present in some species. The premaxillae are represented by nasal branches only; they are not fused with each other, not usually fused to other parts of skull, and do not meet dorsal to the nasal aperture. The palate has a very deep, wide, U-shaped or sometimes V-shaped anterior emargination (Figure 87). The tympanic bullae are either complete, or they are incomplete, i.e. having one or more lacunae (gaps or holes) in the inner face (Figure 88). Deep basisphenoid pits are present. For some species, the condylocanine length (CcL) of the skull is more useful diagnostically than the GLS: CcL = distance from the most posterior point of one exoccipital condyle to the front of the

canine on the same side (Figure 23). The dental formula is $^{1123}/_{3123} = 32$ or $^{1123}/_{2123} = 30$. The anterior upper premolar is very small; the posterior premolar is large and taller than the molars. The postcranial skeleton is, in general, primitive for microbats (Koopman 1994).

Emballonurids vary greatly in their wing morphology, flight and foraging strategies. The four African species for which data are available have medium to high aspect ratios and medium to extremely high wing-loadings and their flight is fast to very fast, and agile with poor manoeuvrability. They can take off from the ground but cannot hover.

Figure 87. Variations in the shape of the anterior palatal emargination in African bats in the family Emballonuridae. (a) Comparatively wide and U-shaped (e.g. *Saccolaimus peli*). (b) Somewhat V-shaped (e.g. *S. peli*). (c) Comparatively wide and U-shaped (e.g. *Taphozous nudiventris*). (d) Comparatively narrow and more V-shaped (e.g. *T. perforatus*). Canine widths drawn to same size.

Figure 88. Differences in the auditory bullae of *Saccolaimus* and *Taphozous*. Each skull has been slightly rotated (right zygomatic arch lower than left) to expose the inner surface of the right bulla. The bullae are (a) complete in *Saccolaimus* and (b) incomplete in *Taphozous*.

Figure 89. Sonograms of echolocation calls of an emballonurid (*Taphozous mauritanus*) showing the diversity of call-shapes associated with echolocation in different circumstances (M. Happold unpubl.). From left to right: calls (a) to (e), a sequence emitted as a bat was released and flew very close to the ground. Calls (f) and (g), two adjacent calls in a sequence emitted as this bat gained height. Call (h), one of a sequence emitted by a bat foraging in vicinity of trees and buildings. Calls (i) to (n), a sequence emitted by a bat foraging in open space, high above ground. Time axis marked at intervals of 10 ms.

The cost of flight is comparatively low, and they forage for long periods at a time in uncluttered open spaces, mainly high above the ground and trees, and they eat their prey while continuing to fly. They appear to be exclusively insectivorous. One African species, *Taphozous mauritanus*, has been recorded foraging up to 550 m above ground (Fenton & Griffin 1997). African emballonurids for which data are available echolocate with search-phase calls that are either multiharmonic CF calls, or shallow linear FM sweeps (Figure 89). In their wing morphology, flight and foraging, and also in some aspects of their echolocation calls, African emballonurids resemble free-tailed bats (*Tadarida*: Molossidae), probably as a result of convergent evolution.

Emballonurids are well adapted for cursorial locomotion. On vertical surfaces, *Taphozous* scuttle sideways like crabs, sometimes with incredible rapidity, and on horizontal surfaces they bounce forwards or sideways like clockwork toys, with the limbs in synchrony (no information for *Saccolaimus* and *Coleura*). During the day, African emballonurids roost in caves, rock crevices, mines, hollow trees and cavernous buildings and one species clings to shaded tree trunks and walls. They cling in contact, head facing down, to vertical or steeply sloping surfaces. Some species roost singly or in small groups; others in colonies of hundreds or thousands. None hibernates. The social and reproductive behaviour of two African species, *T. hildegardae* and *C. afra*, is well known (see profiles). African emballonurids invariably have one young/litter. The reproductive chronologies of African species include restricted seasonal monoestry (*T. hildegardae*, *T. nudiventris*) and bimodal polyoestry (*C. afra*, *T. mauritanus* and perhaps *T. perforatus*). Sperm storage with delayed fertilization has been documented for *T. nudiventris* in Iraq. Delayed implantation has been documented for *T. hildegardae*, and retarded embryonic development (under some circumstances) for *C. afra*. The reproductive biology of the other African species is poorly known.

The geological range of the family Emballonuridae is middle Eocene to early Miocene in Europe, early Miocene to Recent in Africa, Pliocene to Recent in Australia, Pleistocene to Recent in South America and Recent in other parts of the geographic range (Koopman 1984, Archer *et al.* 1991). Fossils from the late Eocene–early Oligocene of Europe are morphologically similar to species in the genera *Taphozous* and *Saccolaimus* (Barghoorn 1977 in Robbins & Sarich 1988).

Emballonurids are found mainly within the tropics, in both the Old and the New Worlds, including islands of the Indian and central Pacific oceans, the Malay archipelago and Australia. They have radiated into rainforests, open woodland savannas and more arid habitats. All of the seven African species occur in the tropics, but two extend northwards and one extends southwards into the temperate regions. Three are

found mainly in savannas, one in both forests and savannas, one in both savanna and arid habitats, one in rainforest, and one is found in all three habitats. No species appears to inhabit montane habitats. A preliminary survey suggests that there are few localities where more than one species has been recorded, but there are some localities where two species occur sympatrically, e.g. *S. peli* and *T. mauritanus* at Avakubi, DR Congo (Hayman *et al.* 1966) and Lagos, Nigeria (Happold 1987); *T. nudiventris* and *T. perforatus* at Luxor, Egypt (Gaisler *et al.* 1972). Three species occur sympatrically at Shimoni, Kenya (*C. afra*, *T. hildegardeae* and *T. mauritanus*). The radiation of emballonurids in Africa has not been as extensive as in South America where there are eight genera and 21 species (data from Simmons 2005).

Emballonurids are regarded as one of the most primitive groups of bats and have, in common with the Pteropodidae, well-developed eyes, long postorbital processes and unfused premaxillae. Cladistic analysis of morphological and molecular characters indicates that the Emballonuridae are a monophyletic family that is outside the clade containing all other microbats. For this reason, the family Emballonuridae is placed by itself in the superfamily Emballonuroidea (Simmons 1998, Simmons & Geisler 1998). Morphological characters analysed by Barghoorn (1977) and evidence from protein electrophoresis and immunology (Robbins & Sarich 1988) support the division of the family into two subfamilies: the Taphozoinae (with *Saccolaimus* and *Taphozous*) and the Emballonurinae (with *Coleura* and all other genera). The separation of *Taphozous* and *Saccolaimus* from the other

genera is supported by hyoid morphology (Griffiths & Smith 1991) and the morphometric analysis of Freeman & Leman (1991). Some taxonomists consider that two of the New World genera should be placed in a third subfamily (Corbet & Hill 1991, Freeman & Leman 1991, Jones & Hood 1993), but only two subfamilies are recognized by Simmons (2005). The subfamily Emballonurinae has been divided into two tribes by McKenna & Bell (1997) and Robbins & Sarich (1988), but the tribes (as defined by McKenna & Bell 1997) are possibly paraphyletic (Dunlop 1998 in Simmons 2005) and therefore no tribes are recognized by Simmons (2005) or here.

The three genera in Africa, and their distinguishing characters in Africa, are:

- Coleura*. FA: 44–53 mm; no radio-metacarpal pouch; tragus parallel-sided (Figure 85a); three lower incisors on each side. One species.
- Saccolaimus*. FA: 87–95 mm; no radio-metacarpal pouch; tragus not parallel-sided (Figure 85b); two lower incisors on each side. One species.
- Taphozous*. FA: 56–79 mm; radio-metacarpal pouch present; tragus not parallel-sided (Figure 85c–f); two lower incisors on each side. Five species.

The subfamilies and genera are presented alphabetically.

Meredith Happold

Subfamily EMBALLONURINAE – Sheath-tailed Bats, Sac-winged Bats, Ghost Bats and others

Emballonurinae Gervais, 1855. In: F. Comte de Castelnau, Exped. Partes Cen. Am. Sud., Zool. (Sec. 7), Vol. 1, pt 2 (Mammifères), p. 62 footnote.

This subfamily contains 11 extant genera of which one, *Coleura*, is represented by one species in Africa and another in the Seychelle Is. Of the ten other genera, seven occur mainly in Central and/or South America and the others are found mainly on the Malay Peninsula, the Malay Archipelago (including Philippines and New Guinea), Caroline

and Mariana Is., Solomon Is., Vanuatu, Fiji and Samoa. Two species of one genus, *Emballoneura*, occur on Madagascar. For further information, see Family Emballonuridae.

Meredith Happold

GENUS *Coleura* African Sheath-tailed Bats

Coleura Peters, 1867. Monatsber. K. Preuss. Akad. Wiss. Berlin 1867: 479. Type species: *Emballonura afra* Peters, 1852.

Coleura is a polytypic genus with two species, one in Africa and Arabia, and one in the Seychelle Is. The latter has also been reported from Zanzibar I., but this record is extremely dubious (Koopman 1993). *Coleura* is distinguished from African members of the genera *Saccolaimus* and *Taphozous* by the following combination of characters: FA: 44–53 mm; no radio-metacarpal pouch; tragus parallel-sided; profile of forehead region of skull (viewed laterally) strongly concave; dental formula $\frac{1123}{3123} = 32$. Craniodental characters of *Coleura afra* are illustrated in Figure 90.

The only species in Africa is *Coleura afra*.

Meredith Happold *Coleura afra*.

Coleura afra AFRICAN SHEATH-TAILED BAT

Fr. Coléoure d'Afrique; Ger. Afrikanische Schiebeschwanz-Fledermaus

Coleura afra (Peters, 1852). Reise nach Mossambique, Säugeth., p. 51. Tete, Mozambique.

Taxonomy Originally *Emballonura afra*. Synonyms: *gallarum*, *kummeri*, *nilosa*. Subspecies: three of dubious validity. Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; smaller than any other African emballonurid (FA: 44–53 mm); three lower incisors on each side; tragus tall and almost parallel-sided; pelage covering all of body; dorsal pelage dark brown; wings brown. Sexes similar in colour; ♀♀ on average slightly larger than ♂♂. Pelage soft, dense; mid-dorsal hairs ca. 5–7 mm. Dorsal pelage medium to dark brown (not grizzled); hairs with paler base. Ventral pelage slightly paler. Head broad with pointed muzzle; sides of face appear swollen; nostrils protrude beyond lower jaw; prominence on lower lip not divided by median groove. Ears brown, subtriangular, tip rounded; antitragus shallow, long, almost reaching corner of mouth. Tragus tall, narrow, roughly parallel-sided with small lobule on posterior margin (Figure 85a). No gular pouch; no black beard. Wings long, narrow, translucent brown to blackish-brown; no radio-metacarpal pouch. Dorsal pelage extending over anterior quarter of interfemoral membrane. Calcars almost as long as tibiae.

Skull (Figure 90) small and delicate for an African emballonurid. Braincase ovoid, elevated above plane of rostrum so dorsal profile of skull (viewed laterally) is concave in forehead region. Postorbital process long, comparatively robust. Sagittal crest weak to well developed anteriorly, absent posteriorly; no occipital helmet. Six lower incisors (cf. four in *Saccolaimus* and *Taphozous*). Further anatomical information in Harrison & Bates (1991) and Dunlop (1997).

Geographic Variation The forms *nilosa* from N Sudan and *gallarum* from Somalia are smaller than *C. afra* from Mozambique, and the pelage is darker in the Nile Valley than in the arid regions to the east. Based on these observations, Koopman (1965, 1975) suggested that *gallarum* and *nilosa* might be subspecies of *C. afra*, but he indicated that the variation was apparently clinal and no subspecies are recognized by Koopman (1994) and Simmons (2005). See also Kock (1969a).

Similar Species Three other African emballonurids have pelage covering all of the body:

Taphozous mauritanus. Two lower incisors on each side. Prominence on lower lip divided by median groove. Wings whitish. Dorsal pelage grizzled. Ventral pelage white or stained yellowish.

Taphozous hildegardeae. Two lower incisors on each side. Prominence on lower lip divided by median groove. Wings mainly white but with brown pigmentation near body. Dorsal pelage pale brown. Throat with blackish beard (♂♂) or white (♀♀).

T. perforatus. Two lower incisors on each side. Prominence on lower lip divided by median groove. Wings white to pale brown. Ventral pelage pale grey, pale greyish-brown to dark greyish-brown; chin

Figure 90. *Coleura afra*. Skull (lateral and dorsal views: BMNH 75.881; ventral view BMNH 15.1.18.3).

and throat usually darker. Adult ♂♂ and ♀♀ with a poorly-defined patch of longer darker hairs on the throat (perhaps not always present).

Distribution Mainly recorded from the Sahel Savanna, Sudan Savanna and Somalia–Masai Bushland and Coastal Forest Mosaic BZs and the Eastern Rainforest–Savanna Mosaic. Recorded from Central African Republic, Sudan, Ethiopia, Djibouti, Somalia, N and E DR Congo, Rwanda, Burundi and East Africa. There are also seemingly isolated populations in West Africa, mainly in the Guinea Savanna BZ and Northern Rainforest–Savanna Mosaic (Guinea-Bissau and Guinea, Côte d'Ivoire, Ghana to W Nigeria), and in the Zambezi Woodland BZ in Angola and Mozambique. Possibly occurs on Zanzibar I. (Kock 1969a): not mapped. A record from Pemba I. 'by Fischer' is rejected by Moreau & Pakenham (1940). Extralimittally: Arabia. Mapped mainly from Kock (1969a) and country checklists.

Habitat Coastal habitats from forests to arid steppes along the Red Sea and Indian Ocean in eastern Africa and the Atlantic in Angola,

Coleura afra

and inland habitats including woodland savannas, drier bushlands, thicket-scrubs and grassy steppes – usually near large lakes or large rivers. Caves, rocky outcrops or similar day-roosts required.

Abundance Common. Sometimes very abundant in vicinity of caves.

Adaptations Wing morphology and flight characteristics: no information. Locomotion over horizontal and sloping surfaces is very rapid, as in other emballonurids. By day, clings, head-down, to the walls of caves and cavities in rocky outcrops, deserted buildings and unused cellars (Rosevear 1965). Prefers dimly lit places (e.g. near entrances of caves). Roosts apart from other species, such as *Taphozous hildegardeae*, *Rhinopoma macinnesi*, *Asellia tridens*, *Triaenops afer* and *Hipposideros caffer*, that sometimes share the same caves.

Foraging and Food Forages by fast-hawking in open spaces. Near the Kenyan coast, feeds mainly on Coleoptera and Lepidoptera, lesser amounts of Hemiptera, Homoptera and Hymenoptera, and some Orthoptera, Isoptera, Neuroptera and Diptera (McWilliam 1987b). Feeds opportunistically on whatever insects are most abundant; consequently there are seasonal changes in diet.

Echolocation Echolocation calls were reported to be relatively long (>10 ms) shallow FM sweeps with the dominant harmonic ca. 28 kHz (Pye 1980, Neuweiler & Fenton 1988). Taylor *et al.* (2005), in Kenya, recorded QCF calls of three bats (one released in open habitat, one released in forest and one flying free), and found considerable variation between these individuals, and within single sequences emitted by each individual. Mean start-frequencies of the three bats, respectively: 32.2, 34.5, 35.3 kHz; mean end-frequencies: 30.7, 31.1, 33.1 kHz; mean peak-frequencies: 31.2 (30–34), 33.3 (30–36), 34.2 (31.5–36.4) kHz; mean call-durations: 7.7 (7.0–8.0), 3.8 (2.9–5.4), 10.7 (8.3–13.0) ms (n = 11, 25, 13 calls, respectively).

The second harmonic is dominant. The calls were often preceded by a short, ascending, vertical ‘spike’. The calls emitted by the bat released in open habitat had lower peak-frequencies and longer durations than those emitted by the bat released in forest.

Social and Reproductive Behaviour Well studied by McWilliam (1987b). Males defend individual feeding territories. Some (perhaps ♀♀) forage in groups. Roosts in very large groups (colonies); East African colonies sometimes exceed 50,000 individuals. During the cool dry season, colony members huddle in very large, homogeneous, mixed-sex aggregations; apparently to maximize thermoregulatory efficiency. In contrast, throughout most of the year, adult ♀♀ roost in discrete clusters together with their young. Adult ♂♂ compete for access to these clusters of ♀♀; usually each cluster has one ♂ but larger clusters may have a dominant ♂ and a satellite ♂ roosting on the periphery. Solitary ♂♂, and groups of bachelor ♂♂, roost at the periphery of the colony. The compositions of clusters of ♀♀ are stable, and their roost-fidelity is very high. Some young, especially ♀♀, remain in their natal clusters for at least a year and up to at least three years – this probably leads to the formation of clusters of related ♀♀. Clustering facilitates thermoregulation, and cluster-members take turns to roost in optimal positions. Competition by ♂♂ for access to clusters of ♀♀ peaks when the ♀♀ come synchronously into oestrus; synchrony favours mating access by the dominant ♂ in each cluster, and minimizes disturbance to the cluster by inter-male competition. This mating system is known as female-defence polygyny (Bradbury & Vehrencamp 1976), and is a type of harem mating system.

Reproduction and Population Structure Litter-size: one. At ca. 4° S (Diani Beach, coastal Kenya), where rainfall is bimodal (insects most abundant in the wet seasons, less abundant in the short dry season and scarce in the long dry season), the reproductive chronology is seasonal bimodal polyoestry without postpartum oestrus (McWilliam 1987b). Almost all ♀♀ give birth, in synchrony, at the beginning of the long wet season in early Apr, lactate through the wet season, and mate at the end of lactation. After this mating period, if the year is a good one, gestation proceeds in ca. 90% of cases, but foetal growth is slower and this gestation is ca. 122 days long – ca. eight days longer than the preceding gestation. In drought years, 40–60% ♀♀ terminate this pregnancy soon after conception. If gestation proceeds, the pregnant ♀♀ give birth in middle of the short wet season (mid-Nov), and lactation extends into the following dry season and is ca. two weeks shorter than the preceding lactation. Whether or not they are lactating, all adult ♀♀ come synchronously into oestrus and mate ca. 4 weeks after the mid-Nov births. Consequently, ♀♀ can be both pregnant and lactating during the short dry season, but insects are moderately abundant in this dry season. Perhaps unexpectedly, the smaller number of young born in the short wet season and suckled by their pregnant mothers throughout most of the short dry season have a better chance of survival than those born in the long wet season and weaned at the start of the long dry season. This reproductive strategy ensures that the most energetically expensive activities (spermatogenesis, competitive mating and lactation) occur when insects are most abundant. Furthermore, selection favours juvenile survival at the expense of female breeding success during the short wet season birth cycle, and vice versa for the other cycle. Also, the option to terminate the more stressful of the two possible pregnancies

when conditions are unfavourable, undoubtedly increases the life-time reproductive success of the ♀♀.

Predators, Parasites and Diseases Ectoparasites include a bug *Eothenes coleurae* (Hemiptera: Polytetidae); a flea *Chiropteropsylla brockmani* (Siphonaptera: Ischnopsyllidae); bat-flies *Penicillidia fulvida* (Diptera: Nycteribiidae), *Raymondia huberi*, *R. seminuda* (Diptera: Streblidae); a tick *Carios boueti* (Acari: Argasidae); and eight species of mites (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Subfamily TAPHOZOINAE – Pouched Bats and Tomb Bats

Taphozoinae Jerdon, 1867. Mammals of India, p. 30.

This subfamily contains four species of *Saccolaimus* and 14 species of *Taphozous*. The *Taphozous*–*Saccolaimus* group has been distinct at least since the Miocene (Robbins & Sarich 1988). See also Family Emballonuridae, Genus *Saccolaimus* and Genus *Taphozous*.

Meredith Happold

GENUS *Saccolaimus*

Pouched Bats

Saccolaimus Temminck, 1838. Tijdschr. Nat. Gesch. Physiol. 5: 14.

Saccolaimus peli.

Saccolaimus is a polytypic genus with four species: *S. peli* in Africa, *S. flaviventris* and *S. mixtus* in Australia and New Guinea only, and *S. saccolaimus*, which is widespread from Bangladesh, India and Sri Lanka through South-East Asia to the Philippines, Indonesia, New Guinea and Australia (Simmons 2005). The African species is distinguished from African species in other emballonurid genera by the following combination of characters: FA: 87–95 mm; no radio-metacarpal pouch, tragus not parallel-sided (Figure 85b); profile of forehead region of skull (viewed laterally) almost straight; tympanic bullae complete (Figure 88a); dental formula: $^{1123}/_{2123} = 30$. Other craniodental characters of the African *Saccolaimus* are illustrated in Figure 91.

Three species, including *S. peli*, are found mainly in tropical forests and woodlands. In contrast, one Australian species (*S. flaviventris*) occurs in almost all habitats from wet and dry sclerophyll forests and open woodlands to shrublands, grasslands and deserts, and extends from tropical to cool temperate regions (Churchill 1998). *Saccolaimus flaviventris* and *S. saccolaimus* (in Australia) are monotocous and seasonally monoestrous (Churchill 1998); the reproductive strategies of the other two species are not known.

The only species in Africa is *S. peli*.

Meredith Happold

***Saccolaimus peli* PEL'S POUCHED BAT (GIANT POUCHED BAT, BLACK-HAWK BAT)**

Fr. Saccolaime de Pel; Ger. Pels Taschenfledermaus

Saccolaimus peli (Temminck, 1853). Esquisses Zool. sur la Côte de Guinée, p. 82. Boutry River, Ghana.

Taxonomy Originally *Taphozous peli*. Synonyms: none. Chromosome number: not known.

Description Large to very large microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; larger than any other African emballonurid (FA: 87–95 mm); two lower incisors on each side; pelage covering all of body except for a narrow band at the posterior of the rump; dorsal pelage usually dark chocolate brown to blackish; wings black; tympanic bullae complete. Males on average lighter and slightly smaller in body measurements than ♀♀. Pelage dense and silky or greasy; dorsal pelage extending laterally to the wing-membrane but posteriorly only to the level of the anus, leaving a narrow band naked; mid-dorsal hairs 6–7 mm. Dorsal pelage usually almost black with isolated pale-coloured hairs, some individuals

dark or reddish-brown, some with silvery-white frosting; hairs unicoloured or with white at tip. Ventral pelage somewhat paler, longer around chest. U-shaped gular pouch present in both sexes between chin and throat, opening anteriorly. Head moderately flat, subtriangular (viewed dorsally); no frontal depression between the eyes; muzzle conical, somewhat flattened, of naked appearance but actually covered with very short, thin hairs. Eyes very large for a microbat. Ears relatively short (26–28% of FA), thick and leathery, pointed; anterior margin almost straight with papillae inconspicuous or absent; posterior margin convex and almost reaching corner of mouth. Tragus broad and short, spatulate, with a pronounced constriction on posterior margin. Antitragus large. Wing and interfemoral membranes black, thick. No radio-metacarpal pouch. Thumb long and thick with a relatively weak claw.

Skull (Figure 91) very large and robust for an African microbat, and somewhat flattened. Profile of forehead region (viewed laterally) very weakly concave (almost straight). Dorsal profile of skull (viewed laterally) almost smoothly convex. Shield shallow but sharply angular. Postorbital processes thick, strongly curved downwards. Sagittal crest well developed; occipital helmet present. Anterior palatal emargination usually broad and U-shaped (occasionally more V-shaped – Figure 87a and b). Tympanic bullae complete (Figure 88a). Upper incisors simple and small. Anterior upper premolar very small, posterior premolar large and taller than the molars. Two lower incisors on each side.

Geographic Variation Apparently none.

Similar Species Only two other African emballonurids have a band of naked skin on the posterior of the rump adjacent to the interfemoral membrane:

Taphozous hamiltoni. Much smaller (FA: 61–71 mm; GLS: 20.9–25.5 mm).

T. nudiventris. Much smaller (FA: 67–79 mm; GLS: 23.2–28.5 mm). Naked area wider.

Distribution Endemic to Africa. Mainly found in the Rainforest BZ (Western, West Central, East Central and South Central Regions); marginally found in Eastern Rainforest–Savanna Mosaic, and one record in the Zambezian Woodland BZ. Known from more than 70 localities in Guinea (Ziama Forest, Diecké Forest; J. Fahr unpubl.), Liberia, Côte d'Ivoire, Ghana, Nigeria, Cameroon, Gabon, Equatorial Guinea, Congo, DR Congo, Uganda, Kenya and Angola. Conspicuously unrecorded from most of the central Congo Basin and it seems unlikely that this is solely a consequence of insufficient sampling in this region.

Habitat The only African emballonurid found mainly in the rainforest zone. Most of the known localities are in lowland, coastal or swamp forests. Also found in mangroves, montane forests, forest–

Figure 91. *Saccolaimus peli*. Skull (NMHN CG 1984-1274, BMNH 65.756).

*Saccolaimus peli*

savanna mosaic, and rarely in miombo woodland and *Isoberlinia* woodland. In the past, various authors stated that *S. peli* avoids the depths of undisturbed forest (e.g. Rosevear 1965, Happold 1987) but it seems more likely that this conclusion is a result of the difficulties associated with sampling high-flying bats in the rainforest zone. *Saccolaimus peli* extensively uses clearings in the forest – probably taking advantage of a higher insect-availability – but also forages above the canopy of closed forest (J. Fahr pers. obs.).

Abundance Widespread and locally common.

Adaptations Wings pointed and narrow; wingspan greater than in any other African microbat. Flies with strong, deliberate wing-strokes; sometimes glides between wing-beats; makes long, hawk-like swoops when pursuing prey. Eyes unusually large, suggesting that vision plays a more important role in orientation and/or capture of prey than in most other insectivorous bats. Roosts during the day in large, hollow trunks of trees and *Borassus* palms (Lang & Chapin 1917b, De Vree 1971, museum data). Clings to the walls of the roost in typical emballonurid fashion, with the belly flat against the surface and the head raised. Two ♂♂ were collected when emerging from a slit-like hole in the trunk of a silk cotton tree *Ceiba pentandra* ca. 27 m above the ground (Coe 1975). Not known to share day-roosts with other species of bats.

Foraging and Food Forages by fast-hawking in open spaces. Early in the evening, individuals are easily observed foraging 5–15 m above ground in forest clearings, above villages and along river valleys through forests; later at night they fly much higher and forage well above the canopy of closed forest (Lang & Chapin 1917b, J. Fahr pers. obs.). The reverse pattern, with high-level foraging at dusk and lower-level foraging later, has also been observed (Kingdon 1974, Coe 1975). Maximum foraging height above ground not known; it is certainly in the range of several dozen or possibly even hundreds

of metres (compare Fenton & Griffin 1997 for data on *Taphozous* sp.). Activity apparently not reduced by moonlight (Lang & Chapin 1917b). Brosset (1966) proposed that individuals do not have fixed home-ranges but forage opportunistically over large areas. Foraging seems to be very efficient – one specimen had its stomach gorged with small insects half an hour after arrival at the foraging area (Lang & Chapin 1917b). Diet largely unknown but small beetles and swarming termites have been documented (Kingdon 1974, USNM).

Echolocation Search-phase calls are multiharmonic, shallow linear FM sweeps. The lower frequencies of the calls are audible to the human ear and have been mistaken for social or contact calls (J. Fahr unpubl.).

Social and Reproductive Behaviour Usually forages in small groups (2–4), although sometimes singly or in aggregations of 12–30 individuals (Lang & Chapin 1917b, Kingdon 1974, J. Fahr pers. obs.). Two ♂♂ were found roosting in one hollow tree (Coe 1975); apparently nothing else is documented about the size and composition of groups that share day-roosts. Adult members of groups roost apart without huddling or forming clusters. Captive bats are not aggressive towards each other. Males scratch their gular pouch with the hindclaws and, in subsequent grooming, transfer the gular secretion to other parts of the body (Kingdon 1974). The yellow secretion was more copious in a ♂ with enlarged testes.

Reproduction and Population Structure Litter-size: one (n = 8). Reproductive chronology not known. North of the Equator in West Africa, pregnancies have been observed in Jul (n = 3) and Dec (n = 3) (USNM, J. Fahr unpubl.). Brosset (1966) reported a ♂ from Gabon (Makokou, 00° 34' N) that was sexually active in Aug (epididymis filled with spermatozooids), and Kingdon (1974) reported ♀♀ from Uganda (without specifying locality) that were just fertilized or had just copulated (uterus distended with semen) in Mar. However, the total number of bats examined during these months, and information for other months, is not available. In DR Congo, pregnant ♀♀ were observed in Jun and Dec (3 out of 10 adult ♀♀) (Lang & Chapin 1917b). Apparently there have been no year-round observations at any one locality and, although the data seem compatible with two seasons of parturition per year (as in some other emballonurids), there is as yet no evidence of polyoestry, and the data also fit alternative chronologies. Lengths of gestation and lactation not known.

Predators, Parasites and Diseases Ectoparasites include bat-flies *Brachytarsina alluaudi* (Diptera: Streblidae), *Basilia aequisetosa* (Diptera: Nycteribiidae) and mites *Carios vespertilionis* (Acari: Argasidae), *Ugandobia taphozous* (Acari: Myobiidae), *Olabidocarpus taphozous* (Acari: Chirodiscidae) and *Rodhainyssus taphozous* (Acari: Gastronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Although mainly found in the rainforest zone, which is increasingly being degraded or destroyed, this species can cope with secondary forests and plantations and consequently is probably less adversely affected by deforestation than other rainforest bats. It has been observed in large numbers even where the surrounding area was heavily degraded (J. Fahr pers. obs.). Major threats: loss and fragmentation of habitat, and destruction of roosts.

Key References Brosset 1966; Kingdon 1974; Lang & Chapin 1917b.**Jakob Fahr****GENUS *Taphozous*****Tomb Bats***Taphozous* E. Geoffroy, 1818. Descript. de L'Egypte 2: 113. Type species: *Taphozous perforatus* E. Geoffroy, 1818.

A polytypic genus with 14 species found only in the Old World. Five species occur in Africa. Of these, two are endemic to Africa, one extends westwards from Africa to islands in the Gulf of Guinea and eastwards to islands in the Indian Ocean, and two extend from Africa across Arabia to NW India or Myanmar (Burma). The other eight species occur in the Oriental and Australasian Regions. *Taphozous* is considered the most highly evolved genus in the family. In Africa, members of this genus are distinguished from African species in other emballonurid genera by the following combination of characters: FA: 56–79 mm; radio-metacarpal pouch present, tragus not parallel-sided; profile of forehead region of skull (viewed laterally) either very weakly concave (almost straight) or strongly concave; tympanic bullae incomplete; dental formula: $^{1123}/_{2123} = 30$. The upper incisors are minute and often absent. Selected craniodental characters of two representatives of the genus are illustrated in Figure 86.

*Taphozous mauritanus*.**Table 17. Key to the African species in the genus *Taphozous*.**

| Pelage coverage
Profile of forehead region of skull | Colour of dorsal pelage | Colour of ventral pelage | Miscellaneous | Species |
|--|--|--|--|-----------------------|
| Rump and lower belly naked
Almost straight | Not grizzled
Dark sepia or rusty-brown | Belly brown
Throat brown | Condylocanine length 20–22 mm
Occipital helmet weakly developed
Naked area less extensive | <i>T. hamiltoni</i> |
| Rump and lower belly naked
Almost straight | Not grizzled
Sepia brown, dark
rusty-brown or
greyish-brown | Belly brown
Throat brown | Condylocanine length
23.0–25.2 mm
Occipital helmet well developed
Naked area more extensive | <i>T. nudiventris</i> |
| Body entirely covered by pelage
Strongly concave | Grizzled
Greyish (sometime
suffused with pale-
brown) | Belly pure white
(or stained yellowish)
Throat white | Very widespread
Roosts on tree trunks, rockfaces,
exterior walls of buildings | <i>T. mauritanus</i> |
| Body entirely covered by pelage
Strongly concave | Not grizzled
Pale greyish-brown | Belly pure white (or stained
yellowish-brown)
Throat black (♂ ♂) or white
(♀ ♀) | Kenya and Tanzania
Roosts in caves | <i>T. hildegardae</i> |
| Body entirely covered by pelage
Strongly concave | Not grizzled
Brown or greyish-brown | Belly pale grey to dark
greyish-brown
Throat usually sepia brown;
darker than belly | Very widespread
Roosts in caves, inside buildings,
in rock crevasses and similar
places | <i>T. perforatus</i> |

Species of *Taphozous* are called tomb bats because some of them often roost in cavernous buildings – including the tombs and temples of Ancient Egypt where they were first discovered – as well as in caves, rock crevices and mine-adits. There is also a tomb bat that roosts on shaded tree trunks and walls. Tomb bats often scuttle out of sight if disturbed, and some of those that roost in cave-like day-roosts sometimes scuttle short distances between their landing (and take-off) sites, and the crevices or other sites in which they roost. Tomb bats occur in most parts of Africa, in woodland savannas, in oases and riverine habitats in arid and desert regions, and marginally in the rainforests.

Two subgenera are recognized:

Taphozous. Body entirely covered by pelage; forehead with deep depression between the eyes; forehead region of skull (viewed laterally) strongly concave; no occipital helmet (Figure 86a). Three species in Africa: *T. hildegardae*, *T. mauritanus* and *T. perforatus*.

Liponycteris. Rump and lower belly naked; forehead without depression; forehead region of skull (viewed laterally) very weakly concave (almost straight); occipital helmet present (Figure 86b).

Two species in Africa: *T. hamiltoni*, *T. nudiventris*.

African species in the genus *Taphozous* can be distinguished by the characters given in Table 17. The species are presented in alphabetical order, irrespective of the subgenus to which they belong.

Meredith Happold

Taphozous hamiltoni HAMILTON'S TOMB BAT

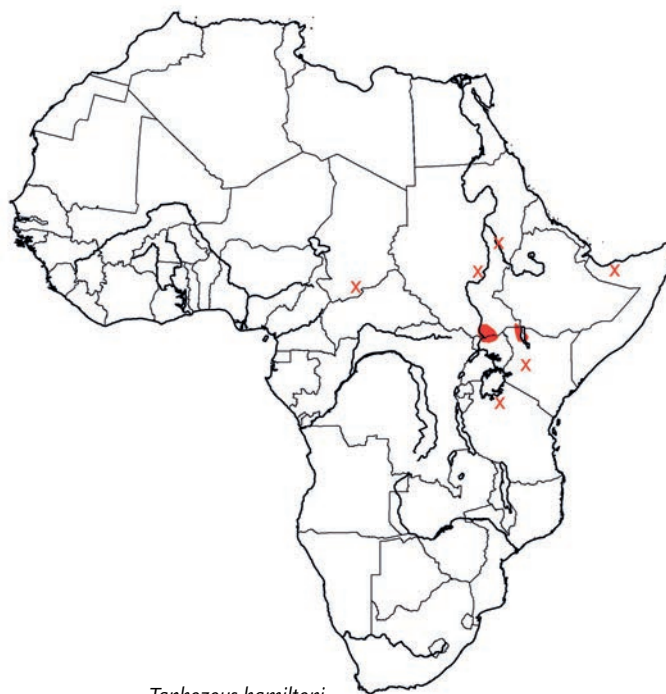

Fr. Taphien de Hamilton; Ger. Hamiltons Grabfledermaus

Taphozous hamiltoni Thomas, 1920. Ann. Mag. Nat. Hist., ser. 9, 5: 142. Mongalla, Equatoria, Sudan.

Taxonomy Synonyms: none. Formerly in subgenus *Taphozous*, but now considered a primitive species of the subgenus *Liponycteris* (Koopman 1975). Chromosome number: not known.

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; two lower incisors on each side; rump and lower belly naked; dorsal pelage dark brown; ventral pelage brown; wings dark brown; condylocanine length: 20–22 mm (cf. *Taphozous nudiventris*). Sexes similar. Pelage sleek; mid-dorsal hairs ca. 6 mm. Dorsal pelage uniformly dark sepia brown to dark rusty-brown (not grizzled); hairs unicoloured or with basal half much paler than terminal half. Rump and flanks naked with clear demarcation between furred and naked areas; naked area ca. 10–20 mm wide mid-dorsally. Ventral pelage paler than dorsal pelage; longer and paler on flanks than mid-ventrally; posterior quarter of ventral surface naked. Gular pouch well developed in both sexes; no black beard. Head moderately flat, subtriangular (viewed dorsally), with long pointed muzzle and a very shallow depression between the eyes. Lower lip with conspicuous grooved prominence. Eyes large for a microbat. Ears subtriangular, backward-pointing, with papillae along the lower inner margin. Tragus broad, axe-head-shaped with pronounced lobule at base of posterior margin; antitragus large, almost reaching corner of mouth. Wings and interfemoral membrane very dark brown; radio-metacarpal pouch present. Hindlimbs naked.

Skull very broad and heavily built for an African emballonurid. Frontal depression shallow. Dorsal profile of skull (viewed laterally) almost smoothly convex; profile of forehead region very weakly concave (almost straight). Postorbital processes long, slender, curved downwards behind orbit. Sagittal crest low; occipital helmet present but weakly developed. Anterior palatal emargination wide and U-shaped. Inner face of tympanic bulla incomplete. Condylocanine length: 20–22 mm.

Taphozous hamiltoni

Geographic Variation None recorded.

Similar Species Only two other African emballonurids have a band of naked skin on the posterior of the rump adjacent to the interfemoral membrane:

Taphozous nudiventris. Naked area usually more extensive. Gular pouch of ♀♀ less developed. Skull with occipital helmet well developed. Condylocanine length: 23.0–25.2 mm.

Saccolaimus peli. Much larger (FA: 87–95 mm, GLS: 28.0–31.6 mm).

Distribution Endemic to Africa. Known only from the Sudan Savanna and Somalia–Masai Bushland BZs. Recorded from Sudan (Koopman 1975), Uganda (BMNH) and Kenya (Kock 1981, BMNH), with isolated records from Sarh (Fort Archambault) in Chad (NMW), Lower Sheikh in Somalia (BMNH 34.9.14.5) and Shanwa in Tanzania (BMNH 21.1.1.14).

Habitat Very poorly known except for the general vegetation zones from which specimens have been collected. These include undifferentiated woodland in Chad, *Acacia* wooded grassland and deciduous bushland near the Blue Nile R. at Sennar, Sudan and *Acacia*–*Commiphora* deciduous bushland and thicket, and semi-desert grassland and shrubland, in the vicinity of L. Turkana, Kenya (terminology: White 1983).

Abundance Not known. Very poorly represented in collections.

Remarks One specimen was ‘found in cracks among rocks’ where the species was reported ‘common’ (BMNH 36.11.4.8 from Lodwar, Turkwell R., Kenya). No other information.

Conservation IUCN Category: Data Deficient.

There are very few records and significant loss of habitat is predicted in the near future, mainly because of farming. Population trend: not known.

Meredith Happold

Taphozous hildegardeae HILDEGARDE’S TOMB BAT

Fr. Taphien de Hildegarde; Ger. Hildegardes Grabfledermaus

Taphozous hildegardeae Thomas, 1909. Ann. Mag. Nat. Hist., ser. 8, 4: 98. Rabai (near Mombasa, Coast Province, Kenya).

Taxonomy Subgenus *Taphozous*. Synonyms: currently none. Subspecies: none currently recognized but the taxonomic status of a population that migrates annually into SE Kenya requires elucidation (see Geographic Variation). Chromosome number: not known.

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; two lower incisors on each side; pelage covering all of body; dorsal pelage pale brown; ventral pelage white; wings mainly white; no gular pouch; adult ♂♂ with blackish throat-patch. Sexes similar in appearance (except for ventral pelage); skulls of ♂♂ reported to be ‘distinctly larger’ than those of ♀♀ (Thomas 1915a) but this needs confirmation. Pelage dense, covering all of body; mid-dorsal hairs 7–9 mm. Dorsal pelage uniformly pale greyish-brown (not grizzled); hairs with white base and brown tip. Ventral pelage of ♀♀ pure white. Adult ♂♂ with a prominent blackish throat-patch or ‘beard’ over a glandular area on the throat; glandular secretions frequently stain the white ventral pelage yellowish-brown. No gular pouch in either sex. Head subtriangular (viewed dorsally) with long pointed muzzle and deep depression between the eyes. Lower lip with conspicuous grooved prominence. Eyes comparatively large for a microbat. Ears subtriangular, backward-pointing, with small papillae along inner margin. Tragus roughly axe-head-shaped with weakly developed lobule at base of posterior margin (Figure 85c). Wings long and narrow, pale with brown pigmentation close to body on dorsal side; radio-metacarpal pouch present in both sexes.

Skull small for an African emballonurid. Frontal depression deep. Dorsal profile of forehead region of skull (viewed laterally) strongly concave. Postorbital processes long and slender. Sagittal crest absent; lambdoid crests low; occipital helmet absent. Anterior palatal emargination wide and U-shaped. Inner face of tympanic bulla incomplete. Two lower incisors on each side.

Geographic Variation Uncertain. A taxonomically distinguishable population immigrates annually (in Nov) to a coastal cave in SE Kenya (in which it establishes a maternity colony), and emigrates in May for an unknown destination (A. N. McWilliam unpubl.). These bats (several hundred adult ♀♀ and a few adult ♂♂) are larger than the non-migrating resident population (FA: 68.2 [67–71] mm, cf. 65.1 [61–67] mm), are heavier with darker dorsal pelage, and the ♂♂ lack yellow tinges on the chest and abdomen. The distribution and taxonomic status of this population (possibly a sibling species) need further investigation.

Similar Species Three other African emballonurids have pelage covering all of the body:

Taphozous mauritanus. Dorsal pelage grizzled; belly and throat pure white (sometimes stained yellowish); no blackish beard.

T. perforatus. Dorsal pelage uniformly dark chocolate brown, sepia brown, greyish-brown or ashy-brown. Belly pale grey, pale greyish-brown to dark greyish-brown; chin and throat usually

*Taphozous hildegardeae*

darker. Adult ♂♂ and ♀♀ with poorly defined patch of longer, darker hairs on the throat (perhaps not always present).

Coleura afra. Three lower incisors on each side. Prominence on lower lip not divided by median groove. FA: 44–53 mm. Wings brown to blackish-brown. Ventral pelage brown.

Distribution Probably restricted to the Coastal Forest Mosaic BZ along the coasts of Kenya and Tanzania (Thomas 1909, Kulzer 1959, Kock 1974a, McWilliam 1982, 1988a, Aggundey & Schlitter 1984, Cockle *et al.* 1998; localities listed by Colket & Wilson 1998). Reported on Zanzibar I. by Kingdon (1974) but not recorded there by Moreau & Pakenham (1940) or Pakenham (1984). Also recorded from two inland localities in Kenya (Harrison 1960; specimens in NMK) but, because these are the only inland records and occur within geographic range and habitat of *T. perforatus*, the identity of the relevant specimens needs confirmation (Kock 1974a). Alternatively, these specimens perhaps represent the migratory population of uncertain taxonomic status (see Geographic Variation); these localities are mapped as question marks.

Habitat Recorded in vicinity of coral-caves in remnant coastal forests, but probably forages in adjacent scrublands and plantations near these caves.

Abundance Populations in caves are encountered infrequently. Populations in two large Kenyan coral-cave systems were estimated at ca. 1000 and 2000 bats (McWilliam 1980), although a viable breeding population in a smaller cave fluctuated between 200 and 400 bats (McWilliam 1982).

Adaptations Aspect ratio not known; wing-loading medium (dry season) to very high (wet season); flight fast and agile; manoeuvrability poor; hovering impossible; can take off from ground with difficulty but, when inside caves, scuttles over floors and climbs walls instead

of attempting to take off from the ground. In vicinity of coast, roosts by day in caves in a narrow band of uplifted Pleistocene coral reef that extends along the East African coast. Prefers to roost in darker recesses of more open chambers. Roosts apart from other species but, in larger cave systems, sometimes roosts adjacent to colonies of *Coleura afra* and *Miniopterus minor*. In smaller caves, very occasionally roosts adjacent to colonies of *Cardioderma cor.* The large, darker chambers of these coral-caves are occupied by *Hipposideros (gigas and/or vittatus)* and *Rousettus aegyptiacus*, and the narrower, deeper recesses by *Trienops afer*, *Hipposideros caffer* and *Rhinolophus landeri* (A. N. McWilliam pers. obs.). Although local movements of banded *T. hildegardeae* were recorded by McWilliam (1982), with the exception of the taxonomically distinguishable immigrant population, this species was resident year round and there were no differences between adult ♂♂ and ♀♀ in the distribution of recaptures between seasons. Does not enter pronounced torpor but, during the cold dry season, solitary ♂♂ were noticeably colder to touch and inactive.

Foraging and Food Limited observations, in degraded forest surrounding a cave used as a day-roost, suggest that foraging is by fast-hawking above treetops or in open spaces, at high levels, between well-spaced trees (A. N. McWilliam pers. obs.). However, foraging locations and behaviour remain poorly known. Although these bats forage throughout the night, their caves also function as night-roosts and ♂♂, in particular, return to diurnal territories (see below). As many as a quarter of the diurnal population can be present during what appears to be a main rest from foraging during the middle of the night. Prey consists mainly of Lepidoptera and Orthoptera, with traces of Homoptera, Coleoptera and Hymenoptera. However, there are seasonal differences and Lepidoptera comprise the major part of the diet during both of the annual wet seasons. Analysis of faecal pellets revealed that, during the wet seasons, 52% of the pellets contained only Lepidoptera, 19% contained only Orthoptera and 29% contained both Lepidoptera and Orthoptera ($n = 165$ pellets). In contrast, during the dry season, 26% of the pellets contained only Lepidoptera, 22% contained only Orthoptera, and 52% contained both Lepidoptera and Orthoptera ($n = 153$; A. N. McWilliam unpubl.). Insects are most abundant during the two periods of peak rainfall (Oct–Dec and Apr–Jun), and ♂♂ accumulate substantial deposits of fat at these times (ca. 30% of body weight between Apr–Jul). These reserves of energy are depleted during competitive mating and the dry seasons when insects are comparatively scarce. With the exception of pregnancy, the weight cycles of ♀♀ are less pronounced than those of ♂♂ because of the energy demands associated with lactation, which normally lasts from Dec to beginning of May. Insects first appear in the diet of juveniles in Mar.

Echolocation No information.

Social and Reproductive Behaviour Roosts in very large groups (colonies) of 100–2000 individuals of both sexes. A study of behaviour and social structure at a day-roost revealed that this species has a polygynous mating system based on the monopolization of favoured roosting sites and also of ♀♀ by successful ♂♂ (McWilliam 1982, 1988a). Consequently, the colony dispersion-pattern is highly structured, with separate areas used as crèches for young bats and roost-sites for ‘bachelor’ ♂♂. The most protected and favoured

sites are retained year round as territories by successful ♂♂, which they mark with scents from glands under their beards, and from the anogenital region. Other ♂♂ are repelled by wing-flicks, 'tcheek tcheek' vocalizations, scent-marking, visual displays, posture changes and attacks with extended forearm and claw. Territorial activities increase during Apr–Jun (including the scent-marking of ♀♀ prior to mating in late Jul), and again during Oct–Dec after the long dry season (for concomitant reproductive data, see below). Most harem ♂♂ roost year-round with up to seven adult ♀♀, although some form multimale groups (including up to four 'satellite' ♂♂) with between 7 and 15 ♀♀. Harems appear generally stable in composition, and there is no consistent segregation of the sexes during parturition and early lactation. Active 'herding' of ♀♀ and young into compact groups, involving forearm attacks and nipping, was a behaviour only carried out by those ♂♂ associated with large clusters of ♀♀, and therefore was more commonly observed in multimale groups. However, some ♀♀ (possibly from smaller territories) move to maternity groups in a warmer outer chamber about a fortnight after parturition while still carrying their young. A second similar move, probably also temperature-induced, occurs at the end of the cold dry season in Sep when rapid growth of foetuses is initiated.

Reproduction and Population Structure Litter-size: one. At ca. 4°S (coastal Kenya), the reproductive chronology is restricted seasonal monoestry with copulation and ovulation (from right ovary) when rainfall is lowest (late Jul to early Aug); gestation normally ca. 140 days; and parturition during the second wet-season (mid- to late Dec). A pronounced delay in the timing of parturition (some still pregnant late Jan to early Feb), following a severe dry season when body condition in ♀♀ was very poor, was linked to a delay in implantation of the blastocyst of some 49 days. Unusually for a mammal, the diapause occurred in the oviduct, where histology showed morulae at the same stage in late Aug and mid-Oct (McWilliam 1982). Testicular regeneration occurs during both wet seasons; weight increase of testes in Apr–Jun and peak

epididymal weights in Jul culminated in copulation; in contrast, the increase in Oct–Dec did not result in reproduction but suggests that *T. hildegardae* was polyoestrous in the past (McWilliam 1988a). Possibly, the maintenance of year-round harems is also linked to vestigial polyoestry. The present monoestrous strategy ensures that both spermatogenesis in the ♂♂, and late-pregnancy and lactation in the ♀♀, coincide with peaks in abundance of insects.

Predators, Parasites and Diseases Ectoparasites include a bed-bug *Loxaspis miranda* (Hemiptera: Cimicidae) and a bat-fly *Brachytarsina alluaudi* (Diptera: Streblidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Vulnerable.

Has a very small geographic range and is threatened by destruction of habitat along the coastal strip and other human activities, including tourism, recreation and disturbing colonies within coastal caves.

Taphozous mauritanus MAURITIAN TOMB BAT

Fr. Taphien de Maurice; Ger. Mauritius-Grabfledermaus

Taphozous mauritanus E. Geoffroy, 1818. Descrip. de L'Egypte 2: 127. Mauritius (Indian Ocean).

Taxonomy Subgenus *Taphozous*. Synonyms: *cinerascens*, *dobsoni*, *leucopterus*. Subspecies: none currently recognized. Chromosome number (South Africa): 2n = 42; aFN = 64 (Rautenbach *et al.* 1993).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; two lower incisors on each side; pelage covering all of body; dorsal pelage grizzled, ventral pelage white; wings white. Sexes similar in colour and size. Pelage sleek, soft and dense, covering all parts of body; mid-dorsal hairs 5–7 mm. Dorsal pelage grizzled dark and pale grey, suffused with pale-brown (fawn) in some individuals, which can make the grizzling indistinct; hairs pale grey or pale greyish-brown at base with band of dark grey across terminal half and pale grey tip. Ventral pelage pure white (sometimes stained yellow). Gular pouch present in ♂♂, present or

absent in ♀♀. No black beard. Head moderately flat, subtriangular (viewed dorsally) with a long, pointed muzzle and a deep depression between the eyes. Lower lip with conspicuous grooved prominence. Eyes comparatively large. Ears subtriangular, backward-pointing, with no papillae on inner margins; antitragus long, shallow, almost reaching corner of mouth. Tragus very broad with terminal half subrectangular and a small lobule at base of posterior margin (Figure 85d). Wings long and narrow; wing-membranes translucent and white with some colourless areas; radio-metacarpal pouch present in both sexes.

Skull small to medium-sized for an African emballonurid. Frontal depression deep. Profile of forehead region of skull (viewed laterally) strongly concave. Postorbital processes long and slender. Sagittal crest usually absent, sometimes poorly developed; no occipital helmet. Anterior palatal emargination U-shaped. Inner face of

tympanic bulla incomplete. Upper incisors minute and sometimes absent. Two lower incisors on each side.

Geographic Variation Uncertain. There appears to be some geographical variation in size (Dengis 1996), but this needs confirmation.

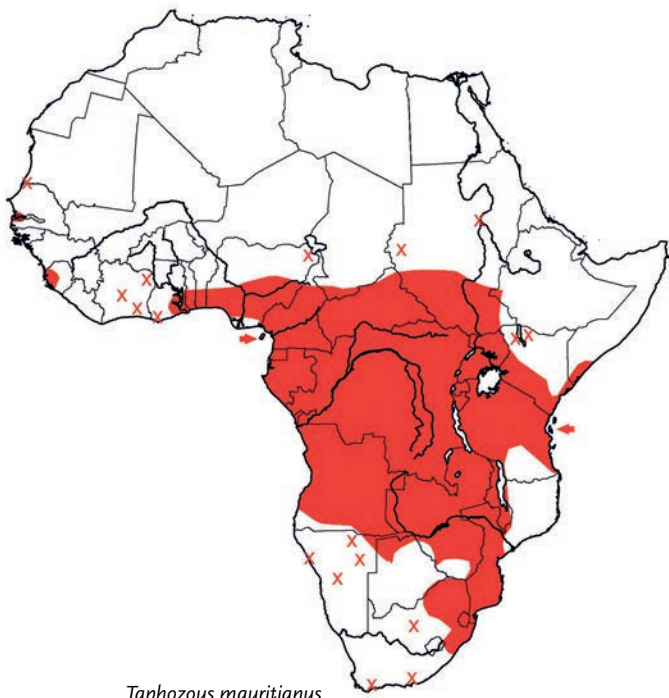

Similar Species Three other African emballonurids have pelage covering all of the body:

Taphozous hildegardeae. Dorsal pelage uniformly pale greyish-brown (not grizzled). Adult ♂♂ with blackish 'beard' on throat, ventral pelage white stained yellowish-brown.

T. perforatus. Dorsal pelage uniformly dark chocolate brown, sepia brown, greyish-brown or ashy-brown (not grizzled). Belly pale grey, pale greyish-brown to dark greyish-brown; chin and throat usually darker. Adult ♂♂ and ♀♀ with poorly defined patch of longer, darker hairs on the throat (perhaps not always present).

Coleura afra. Three lower incisors on each side. Prominence on lower lip not divided by median groove. FA: 44–53 mm. Wings brown to blackish-brown. Ventral pelage brown.

Distribution In Africa, very widely but patchily distributed, mainly in the Guinea Savanna BZ, Rainforest–Savanna Mosaics, Rainforest BZ, southern part of Somalia–Masai Bushland BZ, Coastal Forest Mosaic BZ, Zambezan Woodland BZ and South-West Cape BZ; also a few records in the Sudan Savanna and Sahel Savanna BZs. Distributed from Senegal to Somalia (but not recorded from all countries) and extending southwards to Namibia on the western side of the continent, and to the Cape Province of South Africa on the eastern and southern sides. Extraliminally: islands in Gulf of Guinea (Annobón, São Tomé and Príncipe), and islands of Indian Ocean (Madagascar, Mauritius, Réunion, Aldabra and Assumption). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Taphozous mauritanus

Habitat Woodland savannas and large open areas within rainforests (e.g. Lang & Chapin 1917b), and scattered localities in the Sahel Savanna BZ. Distribution correlates with areas receiving at least 500 mm annual rainfall or, in drier areas, near rivers or swamps (Dengis 1996). Apparently avoids dense forests (e.g. Malbrant & Maclatchy 1949) and montane habitats. Distribution is patchy throughout most of geographic range; records especially sparse around periphery of range. Exploits suburban environments in KwaZulu–Natal (Taylor, P. 1998). Has a wider distribution, and appears to have a wider habitat tolerance, than any other African emballonurid, but its habitat requirements need further investigation.

Abundance Uncertain. Moderately common in collections but population numbers appear low throughout much of its geographic range (see Adaptations). Reported 'very numerous' in the bushveld region north of NE DR Congo (Lang & Chapin 1917b) but no recent reports are available.

Adaptations Aspect ratio medium; wing-loading medium; wing-tip pointed. Flight fast and very agile, manoeuvrability poor, hovering impossible. Usually turns by banking with minimum radius of turn usually >50 cm; stall-and-twist turns possible but rare; able to fly across a 1×1×1 m enclosure, but a complete circuit was observed only once (4 bats, 10 flights each, M. Happold unpubl.). Although able to take off from ground, prefers to dive to gain initial speed for flight and roost sites are selected accordingly. Whirring sound made during flight – perhaps caused by vibration of radio-metacarpal pouch (Lang & Chapin 1917b). By day, clings to tree trunks, rockfaces and exterior walls of buildings, two or more metres above ground, where overhanging branches, rocks or eaves create shade. Often roosts on or near buildings occupied by humans; surprisingly tolerant of humans provided they ignore the bats and do not come too close. Holds on with hindfeet and thumbs; head facing downwards but raised, chest seldom in contact; grizzled pelage provides camouflage on some natural surfaces. Reported to roost with *Coleura afra* in coastal caves (Kingdon 1974) but this observation almost certainly refers to *T. hildegardeae* (see profile); apparently there are no other published records of cave-roosting in *T. mauritanus*. Individuals return to the same roosts each day, and these sites become stained (? urine and/or glandular secretions). In wet weather, they move temporarily leeward and, if possible, shelter under branches, leaves or eaves. In Malawi, does not become torpid (even at 21 °C); instead, remains vigilant using the eyes and seldom echolocating. If large birds fly overhead, or if humans come too close, moves out of sight by scuttling sideways around corners or under branches and eaves at great speed. Only flies to nearby sites if danger comes very close. The importance of constant daytime vigilance to avoid predators, and the concomitant need to avoid torpor, probably limits this species to warm environments. Three captive bats, eating winged termites and seldom flying, did not drink (Happold & Happold 1988). Kidneys well adapted for conservation of water; predicted mean maximum urine concentration is comparatively high (3921 mOsmol/kg) (Happold & Happold 1988). Perceives surroundings during day mainly visually (even in flight), but echolocates at night.

Foraging and Food Forages mainly by fast-hawking in open spaces (Fenton *et al.* 1980, M. Happold unpubl.); wing morphology

Taphozous mauritanus.

and echolocation are primarily adapted for this. However, also forages by chasing insects over walls (Grubb *et al.* 1998), and by taking off and catching butterflies passing their roosts during the day (D. Rushworth in Smithers 1983). Fast-hawking occurs above treetops, between well-spaced trees, over clearings, along cliff-faces and over rivers (5–40 m above the water) (Smithers 1971, Fenton *et al.* 1980, M. Happold unpubl.). Sometimes forages up to 550 m above ground (Fenton & Griffin 1997). Kingdon (1974) reports three hours of intensive activity beginning after dark, followed by long rests (at favoured night roosts) interspersed with short flights. However, foraging sometimes begins at sunset (M. Happold unpubl.). Foraging is characterized by steep dives, up to 10 m, assumed to be pursuits of moths diving evasively in response to the bat's echolocation calls (Fenton *et al.* 1980). Feeds mainly on moths (based on stomach contents examined by Lang & Chapin 1917b), but captive bats also eat beetles, winged termites, flies and many other insects, suggesting that opportunistic feeding would occur if moths were comparatively scarce.

Echolocation In Zimbabwe, one foraging bat emitted multiharmonic CF search-phase calls (second harmonic ca. 25 kHz) followed by shorter, multiharmonic shallow linear FM approach-phase calls and then even shorter, angular shallow/steep FM terminal-phase calls. There were four harmonics – the second was dominant but the first and third contained appreciable energy, especially in the approach- and terminal-phases, and therefore these calls are audible to humans (Fenton *et al.* 1980). Search-phase call-shape (Malawi): typically short, multiharmonic CF or very shallow linear FM; intensity high; bandwidth 0–2 kHz; start-frequency 26–29 kHz (second harmonic); end-frequency 24–27 kHz; call-duration 5–13 ms (five bats foraging or flying in open, 50 calls; M. Happold unpubl.) (Figure 89). While orientating in clutter (near ground, trees, buildings), the calls are steep quasi-linear FM sweeps falling from ca. 30 to 24 kHz (second harmonic); mean duration 2.3–3.9 ms; call repetition-rate 10–27 calls/sec. As bats gain height, calls become narrower in bandwidth, longer in duration and sequences may contain some angular shallow/steep FM sweeps (M. Happold unpubl.). See Taylor (1999a) for data from South Africa and Swaziland.

Social and Reproductive Behaviour Roosts singly (? adult ♂♂ only) or in groups typically of 2–6 (but up to 12) of mixed composition, apparently including several adult ♂♂ and ♀♀ (with or without unweaned juveniles or subadults), but group composition and distance between neighbouring groups need further investigation. Group-members (except ♀♀ with young) roost at least 10 cm apart, and up to several metres apart. They make brief contacts, including climbing-over, but then immediately move apart. Vocalizations include (a) single loud 'ping' emitted in contexts of threat and/or alarm to repel conspecifics that come too close, (b) a three-syllable call emitted at 2–3 second intervals when a group-member returns to the roost area, (c) 'twittering' emitted by mothers and young (sustained if they are kept apart) and (d) several other vocalizations of unknown meaning (Happold *et al.* 1987). Individuals sometimes pursue each other in flight, and fight on the roosts, and they screech in these contexts (Lang & Chapin 1917b). Mating system not known, but fragmentary evidence suggests territoriality with defence of foraging areas, day-roosts and perhaps ♀♀, but the possibility that this indicates resource-defence polygyny and/or female-defence polygyny needs confirmation. Resource-defence polygyny is exemplified by the South American emballonurid *Saccopteryx bilineata* (Bradbury & Vehrencamp 1977). Female *T. mauritanus* fly with their young attached to their underparts until the young are volant (D. Rushworth in Smithers 1971). Juveniles often roost on their mothers' backs.

Reproduction and Population Structure Litter-size: one. Reproductive chronology probably bimodal polyoestry throughout geographic range. At ca. 4°N (DR Congo), limited data (Lang & Chapin 1917b, Verschuren 1957) suggest bimodal polyoestry with births ca. Nov–Dec and ca. Apr–May (perhaps less synchronized than in Kenya and Malawi). No conclusive data for more northern latitudes. At ca. 02°18'S (Masalani, near Kibwezi, Kenya), births occur in Nov (peak of main wet season) and Mar–Apr (little wet season) (O'Shea & Vaughan 1980): polyoestry probable but not confirmed at this locality. At ca. 15°S (Liwonde N. P., Malawi), ♀♀ bimodally polyoestrous with births in early wet season (Nov–Dec) and end of wet season (Mar–Apr) (Happold & Happold 1990a). At ca. 30°S (Durban area, South Africa), ♀♀ are polyoestrous with births in Oct–Dec and Feb or Mar (F. Mackenzie in Taylor, P. 1998). Happold & Happold (1990a) did not state that *T. mauritanus* may be monoestrous in some regions of Africa (as erroneously reported by Dengis 1996); monoestry has not been confirmed in this species.

Predators, Parasites and Diseases Predators include owls (Demeter 1981, Taylor, P. 1998). Roosting behaviour implies danger of predation by hawks, other raptors, snakes and perhaps genets *Genetta* spp. Ectoparasites include bat-flies *Basilia blainvillii*, *Phthiridium integrum* (Diptera: Nycteribiidae) and a mite *Olabidocarpus taphozous* (Acari: Chirodiscidae) (Aellen 1952, Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Taphozous nudiventris NAKED-RUMPED TOMB BAT

Fr. Taphien à ventre nu; Ger. Nacktbauch-Grabfledermaus

Taphozous nudiventris Cretzschmar, 1830. In: Rüppell, Atlas Reise Nordl. Afr., Zool. Säugeth., p. 70. Giza, Egypt.

Taxonomy Subgenus *Liponycteris*. Synonyms (Africa only): *assabensis*, possibly *serratus*. Subspecies: five; one in Africa. Chromosome number (Egypt): 2n = 42; aFN = 64 (Hood & Baker 1986).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; two lower incisors on each side; rump, lower belly and hindlimbs naked; dorsal pelage greyish-brown or dark brown; ventral pelage brown; wings dark brown; condylocanine length 23.0–25.2 mm (cf. *Taphozous hamiltoni*). Sexes similar in colour; ♂♂ on average slightly larger than ♀♀. Pelage sleek; mid-dorsal hairs 6–7 mm. Dorsal pelage uniformly sepia brown, dark rusty-brown or ashy greyish-brown (not grizzled); hairs with basal half cream. Rump and flanks naked with clear demarcation between furred and naked areas; up to one-third of the dorsal surface of the body is naked. Ventral pelage paler than dorsal pelage; posterior third of ventral surface of body is naked. Gular pouch well developed in ♂♂, less so in ♀♀. No black beard. Head moderately flat, subtriangular (viewed dorsally) with long conical muzzle and very shallow depression between the eyes. Lower lip with conspicuous grooved prominence. Eyes comparatively large. Ears subtriangular, backward-pointing, with papillae along the lower inner margin. Tragus axe-head-shaped with pronounced lobule at base of posterior margin (Figure 85e); antitragus large, almost reaching corner of mouth. Wings and interfemoral membrane very dark brown; radio-metacarpal pouch present. Hindlimbs naked.

Skull (Figure 86b) medium-large for an African emballonurid, very broad and heavily built. Frontal depression shallow. Dorsal profile of skull (viewed laterally) almost smoothly convex; profile of forehead region very weakly concave (almost straight). Postorbital processes long, slender. Sagittal crest low; occipital helmet well developed. Anterior palatal emargination wide and U-shaped (Figure 87c). Tympanic bulla with inner face incomplete. Condylocanine length: 23.0–25.2 mm. Two lower incisors on each side.

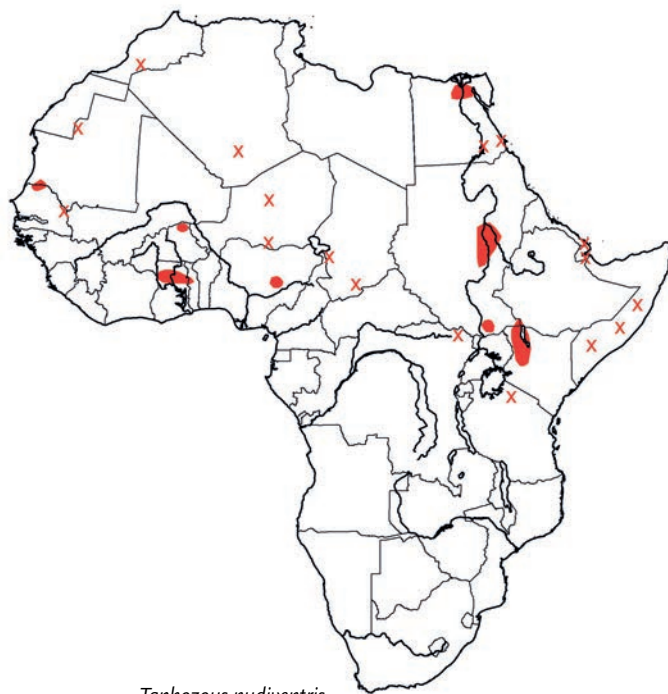

Geographic Variation None recorded in Africa, where only the nominate subspecies is recognized (Koopman 1994).

Similar Species Only two other African emballonurids have a band of naked skin on the posterior of the rump adjacent to the interfemoral membrane:

Taphozous hamiltoni. Naked area usually less extensive. Gular pouch of ♀♀ well developed. Skull with occipital helmet poorly developed; condylocanine length: 20–22 mm.

Saccolaimus peli. Much larger (FA: 87–95 mm; GLS: 28.0–31.6 mm).

Distribution In Africa, recorded from the Sahara Arid, Sudan Savanna, Guinea Savanna and Somalia–Masai Bushland BZs. Distributed from Morocco, Mauritania and Senegal, to Egypt, Eritrea, Djibouti and Somalia, with a narrow southward extension through S Sudan, NE DR Congo and Kenya to Tanzania. Recorded from Guinea-Bissau by Seabra (1900) and Veiga-Ferreira (1949); however, Seabra's identification has not been confirmed and Veiga-Ferreira's record refers to *T. perforatus* (Lopes & Crawford-Cabral 1990). Its occurrence in Gambia is unproven although plausible (Grubb *et al.* 1998). The African distribution appears very disjunct: there are some clusters of localities and many isolated localities. Not known to what extent this reflects insufficient sampling and/or the isolated nature of suitable habitats. Extraliminally: eastwards across

Taphozous nudiventris

Arabian Peninsula, Iran, Afghanistan, Pakistan and India to Myanmar. Mapped from country checklists (see order Chiroptera), Kock 1969a, other literature and museum records.

Habitat Woodland savannas including undifferentiated woodland, *Isoberlinia* woodland, *Acacia–Commiphora* bushland and thicket, and more arid habitats including semi-desert grasslands and shrublands, and deserts. Very little known about habitat requirements, but the distribution is probably restricted by the availability of both flying insects and day-roosts (see below): possibly this species was more abundant and widespread when northern Africa was less arid.

Abundance No information.

Adaptations Aspect ratio high; wing-loading extremely high; wing-tip pointed; flies very fast with great agility but poor manoeuvrability (Rosevear 1965, Norberg & Rayner 1987). Roosts by day in crevices and narrow fissures between rocks or stone blocks, in caves, inselbergs, sandstone hills, wells, old ruins, mosques and the ancient Egyptian temples and tombs of the Nile Valley, including Karnak (Hoogstraal 1962, Gaisler *et al.* 1972, Qumsiyeh 1985, Happold 1987). Day-roosts may have an unpleasant, pungent smell (to humans). Tolerates quite bright light in roosts. April temperatures recorded near roosting bats in Egypt ranged from 23 °C in a mosque to 35 °C in an occupied crevice at Karnak (cf. 37 °C outside in shade) (Gaisler *et al.* 1972). *Rhinopoma hardwickii*, *Asellia tridens*, *Nycteris thebaica* and *Rousettus aegyptiacus* also roosted in the temple complex at Karnak, but each species in a different place. In Iraq, spends summer in cool buildings and caves: moves to old buildings with wooden or rush roofs for hibernation during winter (Al-Robaae 1968). Accumulates fat prior to hibernation. In Pakistan, makes seasonal migrations between summer and winter day-roosts, accumulates fat towards end of monsoon and spends winter in torpor (Roberts 1977). In India and East Africa, fat also accumulates seasonally despite lack of hibernation there (Kingdon 1974). No further information for Africa, where this species has received little attention.

Foraging and Food Forages by fast-hawking in open spaces. Foraging more than 100 m above ground has been inferred from erratic flight paths by *T. nudiventris* in India (Siefer & Kringer 1991 in Fenton & Griffin 1997). Prey includes beetles, moths, grasshoppers, cockroaches, crickets and winged-ants (Pearch *et al.* 1999). Becomes particularly numerous in Gharbiya Province, Palestine during Jul–Aug when Cotton Leaf-worm moths invade cotton fields, and large quantities of moth scales are found in the bats' stomachs at this time (Madkour 1977 in Qumsiyeh 1985).

Echolocation No information for this species in Africa.

Social and Reproductive Behaviour Roosts gregariously; becomes very active ca. 30 minutes before sunset and emerges from the roost ca. 15 minutes after sunset. One colony in Egypt comprised ca. 50 individuals (Gaisler *et al.* 1972); 2000 recorded in Pakistan (Roberts 1977). In Iraq, colonies are of mixed composition throughout most of year. When ♀♀ approach time of parturition, ♂♂ leave or are driven away (sometimes to roosts 100–300 m away) where they are found in groups of 5–10. The ♂♂ rejoin the ♀♀ after the young become volant

(Al-Robaae 1968). Maternity colonies contain 200–1000 ♀♀. Large nuclear colonies with small colonies nearby have also been recorded in Pakistan (Roberts 1977). According to Al-Robaae (1968), the young bat clings to its mother's back for two weeks, then roosts beside her and remains with other young while she forages. According to Roberts (1977), the young remains attached to a nipple for 3–4 weeks, then clings to its mother's flank or back while she forages until eight weeks old. Young begin flying within and near the day-roost when five weeks old. Weaning occurs during sixth week. When foraging away from day-roost, young stay close to mother even after weaning.

Reproduction and Population Structure Litter-size: one. In Iraq, the reproductive chronology is restricted seasonal monoestry, with sperm storage and delayed fertilization (Al-Robaae 1968); no conclusive data for Africa. In Iraq, copulation occurs in Sep–Oct shortly before hibernation. Sperm are stored in the ♀ until late Mar when hibernation ends and ovulation and fertilization take place. Young are born nine weeks later. All young are born during a ten-day period in late May: they are blind, naked, FA: 25–30 mm, HB: 45–50 mm. Eyes open after one week. Growth rapid. Insects in stomach by seven weeks. Reproductive chronology in Pakistan is also restricted seasonal monoestry with copulation in Sep, emergence from winter-roosts at beginning of Mar, birth of young in mid-Apr (Roberts 1977).

Predators, Parasites and Diseases Predators include Barn Owls *Tyto alba* in Palestine (Dor 1947 in Qumsiyeh 1985) and hawks that capture the bats as they leave their roosts in Pakistan (Roberts 1977). Ectoparasites in Africa include bed-bugs *Leptocimex vespertilionis*, *L. duplicatus*, *Stricticimex puylaerti* (Hemiptera: Cimicidae); a flea *Xenopsylla conformis* (Siphonaptera: Ischnopsyllidae); ticks *Carios vespertilionis*, *C. boueti*, *C. confusus* (Acari: Argasidae); and a mite *Steatonyssus sudanensis* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Taphozous perforatus EGYPTIAN TOMB BAT

Fr. Taphien perforé; Ger. Ägyptische Grabfledermaus

Taphozous perforatus E. Geoffroy, 1818. Descrip. de L'Egypte 2: 126. Kom Ombo, between Edfu and Aswan, Upper Egypt.

Taxonomy Subgenus *Taphozous*. Synonyms in Africa: *haedinus*, *maritimus*, *rhodesiae*, *senegalensis*, *sudani*, *swirae*. Extraliminally: *maritimus*. Subspecies: four (three in Africa); boundaries unclear. Harrison (1958, 1962) considered *sudani* to be a distinct species, a view not shared by more recent authors (Rosevear 1965, Kock 1969a, Hayman & Hill 1971, Koopman 1975, Simmons 2005). Chromosome number (Egypt): $2n = 42$; $aFN = 64$ (Yaseen *et al.* 1994).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from middle of dorsal surface of interfemoral membrane; two lower incisors on each side; pelage covering all of body; dorsal pelage not grizzled; ventral pelage pale grey to dark greyish-brown; wings almost white to pale brown. Sexes similar. Pelage soft, fine, silky; covering all parts of body; mid-dorsal hairs 6–7 mm. Dorsal pelage uniformly dark chocolate brown, sepia brown, greyish-brown or ashy-brown; hairs white at base. Ventral pelage pale grey, pale greyish-brown to dark greyish-brown; chin and throat usually sepia brown and darker than dorsal or ventral pelage. Adult ♂♂ and ♀♀ with a poorly defined patch of longer darker hairs on the throat (perhaps not always present). No gular pouch in either sex according to Rosevear (1965), Hayman & Hill (1971) and Harrison & Bates (1991), but Rosevear mentions that a shallow fold of skin or merely a crescentic mark may be present. In contrast, Koopman (1975) implies that a gular pouch is present in some ♂♂ (see Geographic Variation). Head moderately flat, subtriangular (viewed dorsally) with long pointed muzzle and deep depression between the eyes. Eyes comparatively large for a microbat. Lower lip with conspicuous grooved prominence. Ears subtriangular, backward-pointing, with small papillae on lower inner margin. Tragus axe-head-shaped with poorly developed lobule at base of posterior margin (Figure 85f). Wings variable: almost white in individuals with darker brown dorsal pelage, to pale brown in individuals with paler ashy-brown dorsal pelage. Radio-carpal pouch present in both sexes. Interfemoral membrane pale brownish.

Skull (Figure 86) small for an African emballonurid. Frontal depression deep. Profile of forehead region of skull (viewed laterally) strongly concave. Postorbital processes long and slender. Sagittal crest absent, no occipital helmet. Anterior palatal emargination comparatively narrow, and more angular and more V-shaped than in other African *Taphozous* (Figure 87d). Inner face of tympanic bulla incomplete. Two lower incisors on each side.

Geographical Variation Four subspecies are recognized in Africa by Simmons (2005), but their boundaries (based on Koopman 1994) and diagnostic characters are not clear.

T. p. senegalensis: West Africa.

T. p. perforatus: Egypt and N Sudan.

T. p. sudani: C and S Sudan, E DR Congo, Botswana and Zimbabwe.

T. p. haedinus: Tanzania to Ethiopia and, extraliminally, across S Asia to India.

Similar Species Three other African emballonurids have pelage covering all of the body:

Taphozous mauritanus. Dorsal pelage grizzled (salt and pepper effect); ventral pelage pure white (sometimes stained yellowish).

T. hildegardeae. Dorsal pelage uniformly pale greyish-brown. Adult ♂♂ with blackish 'beard' on throat, ventral pelage white stained yellowish-brown. Adult ♀♀ with throat and belly pure white.

Coleura afra. Three lower incisors on each side. Prominence on lower lip not divided by median groove. FA: 44–53 mm. Wings brown to blackish-brown. Ventral pelage brown.

Distribution In Africa, found along Nile Valley in the Sahara Arid BZ and in some parts of the Sahel Savanna, Sudan Savanna, Guinea Savanna, Somalia–Masai Bushland, Coastal Forest Mosaic and Zambezi Woodland BZs, and in the Northern and Eastern Rainforest–Savanna Mosaics. Not recorded from the Rainforest BZ except in NE DR Congo. Except along the Nile Valley, the distribution appears very disjunct (possibly because of insufficient sampling and/or the absence of suitable day-roosts). In West Africa, recorded from Mauritania, Senegal, Mali, Ghana and E Burkina to NW Nigeria. On eastern side of Africa, recorded contiguously from Egypt, Sudan, NE DR Congo, Uganda, NW Kenya and the Ethiopian Rift Valley to the Red Sea in Djibouti and NW Somalia, and there are apparently isolated populations in E Sudan, the Ethiopian Highlands, C to SE Kenya, Tanzania, S DR Congo to N Zambia, the Okavango Swamp of N Botswana, and the low-lying area of S Zimbabwe and E Botswana. Over much of its wide distribution in Africa, records are

Taphozous perforatus

extremely sparse. Extraliminally: S Arabia, Jordan, S Iran, Pakistan and NW India.

Habitat Mainly open woodland savannas, including *Acacia* woodland, *Isoberrinia* woodland, *Acacia–Commiphora* bushland and thicket, and miombo and mopane woodlands, where suitable day-roosts are present. Also recorded from flooded savanna in the Nile Delta, in seasonally moist habitats along the Nile Valley, in rainforest–savanna mosaic, in East African coastal forest mosaic, and in the Okavango Swamp, Botswana. There are some records within the rainforest zone in NE DR Congo, but no details are available. Near the confluence of the Shashi and Limpopo Rivers in Zimbabwe, *T. perforatus* was found near a range of sandstone hills with *Acacia* woodland on the flat country, and well-developed riverine woodland along the seasonally dry river bed (Smithers 1983). Evidently avoids forests, montane habitats, semi-deserts and deserts.

Abundance Uncertain. Over much of its wide distribution, records are extremely sparse, e.g. in East Africa, only one specimen published from Uganda (Kock 1974b), two from Tanzania (Allen & Loveridge 1933, Harrison 1961) and seven from Kenya (Aggundey & Schlitter 1984). Also, comparatively poorly represented in museum collections. In contrast, large numbers (e.g. ca. 200) have been reported from day-roosts in the Nile Valley in Egypt (Gaisler *et al.* 1972, Qumsiyeh 1985) and Hoogstraal (1962) reports it as one of the most common bats in Egypt. Also, a colony of 150–200 was found in NE DR Congo (Lang & Chapin 1917b) and one of >100 in S DR Congo (Anciaux de Faveaux 1978).

Adaptations Aspect ratio medium; wing-loading medium-high. Based on wing morphology, flight-speed estimated to be ca. 8.0 m/sec (Rydell & Yalden 1997), which is medium for bats. By day, roosts in caves, crevices in rocky outcrops and old buildings, including Egyptian pyramids, tombs and other ancient monuments, gaining access by scuttling and climbing as well as by flying. Unlike *T. mauritanus* which roosts in the open, *T. perforatus* roosts tucked away in darkened narrow crevices in rocks or brickwork. Sometimes roosts quite close to the ground (Hoogstraal 1962).

Foraging and Food Forages by fast-hawking. Based on analysis of faeces (Rydell & Yalden 1997), the diet comprises predominantly, in order of priority, moths (56% by volume), termites (14%), beetles (10%) and, to a lesser extent, crickets and katydids (8%), bugs (3%), lacewings (2%), ants (1%) and flies (1%).

Echolocation No information.

Social and Reproductive Behaviour Unlike the less gregarious *T. mauritanus*, *T. perforatus* roosts in groups of several individuals to at least 200 (see Abundance), with individuals huddled together in dense associations (Lang & Chapin 1917b, Hoogstraal 1962). Group-members scuttle and crawl about, but Lang & Chapin (1917b) noted that they never crawled over each other.

Reproduction and Population Structure Litter-size (Egypt, Nigeria, Zimbabwe): one ($n = 19$). Reproductive chronology uncertain. At 25°41'N (Luxor, Egypt), 16 of 16 ♀♀ were in advanced pregnancy in Apr (no data for other months) (Gaisler *et al.* 1972). At 13°04'N (Sokoto, N Nigeria), 6 of 6 adult ♀♀ were lactating in mid-Jun (wet season) and, of these, one was examined histologically and found to be in early pregnancy (no data for other months) (Harrison 1958). This suggests that the chronology in N Nigeria is seasonal polyoestry with postpartum oestrus, but the number of litters/year, the timing of other births and the proportion of ♀♀ that have more than one litter/year, are not known. In Zimbabwe, two pregnant ♀♀ were reported in Nov (Smithers & Wilson 1979). The data from Nigeria and Zimbabwe indicate that at least some births occur at the beginning of the unimodal wet seasons, and that there are boreal and austral cycles. Data from elsewhere, summarized by Anciaux de Faveaux (1978), are not conclusive.

Predators, Parasites and Diseases Predators include Spotted Eagle-owls *Bubo africanus* (Demeter 1982), and probably Lanner Falcons *Falco biarmicus*, which have been observed feeding on bats emerging from a quarry where *T. perforatus* was known to roost (Butler 1905, D. Kock pers. comm.). Ectoparasites include fleas *Xenopsylla cheopis* (Siphonaptera: Pulicidae), *Araeopsylla wassiffi*, *Chiropteropsylla aegyptia*, *C. brockmani* (Siphonaptera: Ischnopsyllidae); bat-flies *Phthiridium integrum* (Diptera: Nycteribiidae), *Brachytarsina diversa*, *B. alluaudi* (Diptera: Streblidae); ticks *Carios vespertilionis*, *C. boueti*, *C. confusus*, *Alectorobius salahi* (Acari: Argasidae); and mites *Steatonyssus* sp. (Acari: Macronyssidae), *Ugandobia barnleyi* (Acari: Myobiidae), *Alabidocarpus taphozous* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984). Dakar bat 249 virus has been isolated from *T. perforatus* (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Family NYCTERIDAE
SLIT-FACED BATS

Nycteridae Van der Hoeven, 1855. Handb. Dierkunde, 2nd edn., 2: 1028.

| | | |
|-----------------------|-----------------|--------|
| Nycteris (13 species) | Slit-faced Bats | p. 440 |
|-----------------------|-----------------|--------|

All nycterids belong to the genus *Nycteris*. There are 16 extant species: 13 occur in Africa, one in Madagascar and two in South-East Asia (Simmons 2005). They are found mainly in rainforests and woodland savannas, but some species inhabit semi-arid habitats. Nycterids are unique in having a deep longitudinal cleft on the head (from the forehead to the nostrils), which is bordered by fleshy outgrowths whose outlines are usually obscured by the pelage (Figure 32g). Like the noseleaves on the muzzles of bats in the families Rhinolophidae, Hipposideridae, Megadermatidae and Rhinopomatidae, these outgrowths play a role in echolocation. Nycterids are also distinguished by a long tail that is completely enclosed by a very large interfemoral membrane and which terminates in a uniquely Y-shaped or T-shaped cartilaginous process (Figure 33g). None are considered to be pests.

African nycterids are very small to medium-sized microbats with moderately long, soft, loose, fluffy pelage, usually brown or grey, occasionally orange. Males and ♀♀ are similar in size and colour. The body is small and compact; the shape of the head is obscured by

pelage. The muzzle has a deep longitudinal cleft; the nostrils are located in the anterior end of this cleft, and the cleft expands into a deep pit on the forehead. The noseleaf is comprised of fleshy outgrowths along the margins of the cleft; its shape is not used diagnostically. The ears are enormous! They are longer than the length of the head, rounded and are united at the base by an inconspicuous low membrane. The tragus is well developed and its shape is an important diagnostic character. The eyes are minute. The wings are large and broad; the second finger has a long metacarpal but no phalanges. The hindlimbs are relatively long with small soles, short toes and small claws; the toes (except hallux) have three phalanges. The tail is relatively long (44–52% of TL), and is completely enclosed by a very large interfemoral membrane, which is supported and manipulated by long calcars and the Y-shaped or T-shaped terminal process of the tail. There are no pubic nipples. The interfemoral membrane is reinforced by numerous strands of collagen fibres, which form patterns of broken and/or unbroken but dotted transverse lines across the membrane. The skull is long and narrow, with a deeply concave frontal shield in the interorbital region; the shield is formed by the fusion of the postorbital processes

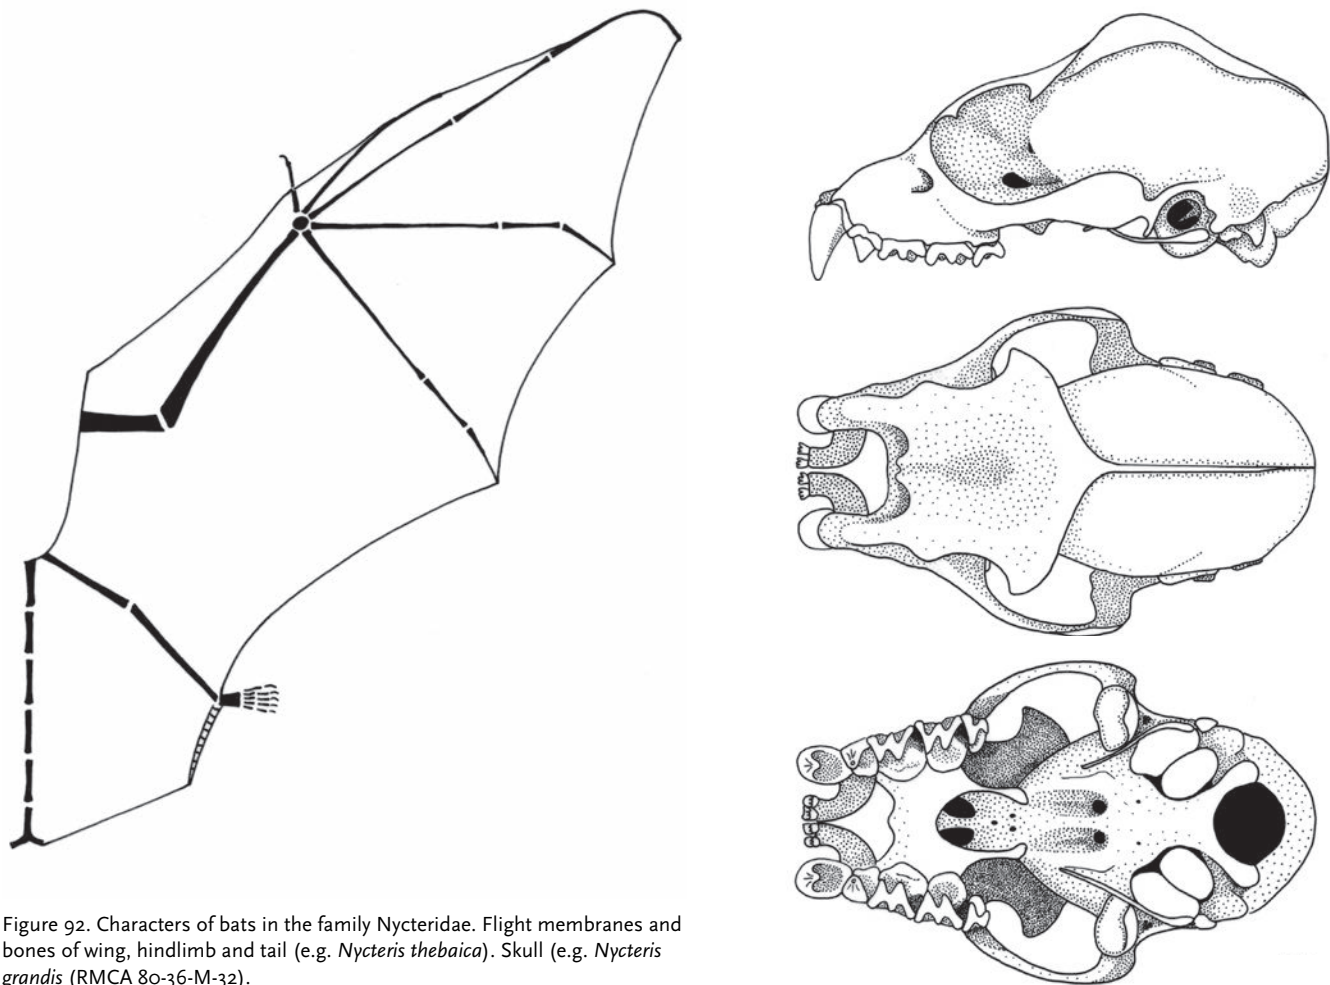

Figure 92. Characters of bats in the family Nycteridae. Flight membranes and bones of wing, hindlimb and tail (e.g. *Nycteris thebaica*). Skull (e.g. *Nycteris grandis* (RMCA 80-36-M-32).

with broad supraorbital ridges. Selected external and craniodental characters of representatives of the genus are illustrated in Figure 92 but there are important inter-specific variations in dentition (see below). Posteriorly, the frontal shield rises to the most elevated part of the skull where it merges with the sagittal crest. The cleft or 'slit' in the face leads into a large chamber supported by the frontal shield. The sagittal crest is usually low or absent (but well developed in two species) and there are no lambdoid crests. The nasal branches of the premaxillae are lost; the palatal branches are partly developed and not fused to each other but are lightly fused to the maxillae and other bones of the palate; they may fill, or only partly fill, the space between the maxillae. Skull characters are not as useful as external characters and dental characters for distinguishing between species of *Nycteris*, and therefore skulls are not described in the species profiles. The dental formula is $2^{113}/_{3123} = 32$. The karyotypes of nycterids are characterized by high fundamental numbers (aFN) compared to other families of bats (Lee *et al.* 1989).

The five species of African nycterids for which data are available have very low aspect ratios and low to very low wing-loadings (very low in all but one species). They can fly slowly with great manoeuvrability, hover, take off from the ground (even when carrying a young bat or heavy prey) and they can turn around in very confined spaces. These adaptations enable nycterids to forage close to the ground and in dense vegetation. Because of their wing morphology, flight is energetically expensive, so they spend minimal time in flight. Although they sometimes forage by slow-hawking, they are usually fly-catchers and perch-hunting gleaners and often carry larger prey back to the perch before eating it. Most species are insectivorous, feeding on a wide variety of taxa, but one African species (*Nycteris grandis*) also eats small vertebrates. Prey is detected from sounds made by the prey as well as by echolocation. Nycterids are referred to as 'whispering' bats because they emit multiharmonic CF echolocation calls of short duration and low intensity (Griffin 1958, Neuweiler 1989). These calls are particularly suited for densely cluttered environments. Nycterids can hover and glean prey from vegetation and other surfaces and, because they can take off from the ground, they can land to attack non-volant prey. However, they are unable to scuttle over the ground and they cannot climb. During the day, nycterids roost in hollow trees, caves, mines, buildings, road culverts, hollow logs, abandoned burrows and similar semi-dark places. They hang freely from footholds on horizontal ceilings, and maintain a space between adult individuals. Their exceptional manoeuvrability enables them to fly into confined spaces to find roosts inaccessible to other bats. They perform an aerobatic somersault in mid-air in order to gain a holdfast from which to hang. Nycterids do not hibernate.

The social behaviour and mating systems of nycterids are not well known. Bats of one species appear to be mainly solitary; some apparently form monogamous family groups (Hill & Smith 1984), and it seems likely, from the very limited data, that some might establish harems (but this needs confirmation). All nycterids for which data are available are monotocous. Surprisingly, the reproductive chronology of only one African species (*N. thebaica*) has been ascertained with

certainty, and only in South Africa where it exemplifies restricted seasonal monoestry. Polyestry has been reported for two species (*N. hispida* and *N. macrotis*) in Tanzania, but the chronologies of these species are not known in detail. Bernard (1982a) and Bernard & Cumming (1997) suggest that polyestry is the ancestral strategy for nycterids and that monoestry evolved as an adaptation to higher latitudes where conditions are optimal only once per year.

The geological range of the family Nycteridae is not known (Koopman 1984). It has been suggested that there have been at least two major dispersals of the genus in the Old World tropics (Thomas *et al.* 1994). First, the *arge* group (see below) dispersed from Africa, during a Miocene or Pliocene pluvial period, across forests that spread uninterrupted from Africa to eastern Asia and later, when drier conditions prevailed, two South-East Asian species became isolated from the remainder in Africa. Secondly, *N. thebaica*, which is adapted to xeric conditions, dispersed from Africa into Israel and Arabia. In Africa, adaptive radiation has been extensive: three species are found mainly in rainforest, six occur in both forests (including rainforest) and woodland savannas, three occur mainly in woodland savannas, and one (*N. thebaica*) occurs in diverse habitats including clearings in rainforest, woodland and grassland savannas, and oases and riverine habitats in arid regions. Four species (31%) have been found in montane habitats, but no species are mountain specialists. It is not uncommon to find more than one species at any one place, and 4–5 species have been recorded at several localities. For example:

- Comoé N. P., Côte d'Ivoire (Sudan Savanna BZ): *N. arge*, *N. intermedia*, *N. hispida*, *N. macrotis*, *N. nana* (Fahr & Kalko 2010).
 Ituri Forest, E DR Congo (Rainforest BZ): *N. arge*, *N. grandis*, *N. hispida*, *N. intermedia*, *N. nana* (Van Cakenberghe & De Vree 1985, 1993).
 Taï N. P., Côte d'Ivoire (Rainforest BZ): *N. arge*, *N. grandis*, *N. intermedia*, *N. major*, (Fahr & Kalko 2010).
 Adiopodoumé, Côte d'Ivoire (Rainforest BZ): *N. arge*, *N. hispida*, *N. intermedia*, *N. macrotis* (Van Cakenberghe & De Vree 1985, 1993).
 Avakubi, NE DR Congo (Rainforest BZ): *N. arge*, *N. hispida*, *N. intermedia*, *N. major* (Van Cakenberghe & De Vree 1985, 1993).
 Liwonde N. P., Malawi (Zambezian Woodland BZ): *N. grandis*, *N. hispida*, *N. macrotis*, *N. thebaica* (Happold & Happold 1997).

Based on morphological data, the family Nycteridae was placed in the superfamily Rhinolophoidea together with the families Rhinolophidae, Hipposideridae and Megadermatidae (Simmons 1998, Simmons & Geisler 1998), but more recent molecular studies have contradicted many groupings based on morphological data and, pending resolution of the controversies, no chiropteran superfamilies are recognized by Simmons (2005). The systematics of African nycterids has been revised by Van Cakenberghe & De Vree (1985, 1993, 1998).

All nycterids belong to the genus *Nycteris*.

Meredith Happold

GENUS *Nycteris*

Slit-faced Bats

Nycteris G. Cuvier & E. Geoffroy, 1795. Mag. Encyclop. 2: 186. Type species: *Vespertilio hispidus* Schreber, 1774 (*nomen nudum*, validated by Opinion 111 of the International Commission on Zoological Nomenclature).

Nycteris thebaica.

This genus has 16 extant species of which 13 occur in Africa. There are no other genera in the family Nycteridae and the characters of the genus *Nycteris* are given in the family profile.

African species of *Nycteris* can be distinguished by the combinations of characters given in Table 18, but see also additional information under Similar Species. Characters of particular diagnostic value are:

Shape of upper incisors. Bicuspid (Figure 93a) or tricuspid (Figure 93b).

Relative size of the posterior lower premolar. Can be large (reaching at least half the height of the anterior lower premolar Figure 93c) or small (reaching less than half height of anterior lower premolar (Figure 93d and e).

Shape of posterior margin of the tragus in conjunction with the shape of the tragus. The posterior margin can be smoothly convex and the shape semi-lunate (Figure 93f) or smoothly convex and the shape narrow (not semi-lunate) (Figure 93g); or the posterior margin can be deeply notched and the tragus inverted pear-shaped (Figure 93h), or the posterior margin can be concave or slightly concave (Figure 93i).

FA (length of forearm). Mean \pm 1 S.D. is given for some species.

E (length of ear). In African species, mean length ranges from 21.1–32.0 mm, so 21.1–24.7 mm is comparatively short, 24.8–28.3 mm is medium, and 28.4–32.0 mm is comparatively long.

Figure 93. Diagnostic characters of species of *Nycteris*. (a) Upper incisors bifid (e.g. *N. capensis*). (b) Upper incisors trifid (e.g. *N. hispida*). (c) Posterior lower premolar relatively large (e.g. *N. intermedia*). (d) and (e) Posterior lower premolar relatively small (e.g. *N. macrotis*, *N. thebaica*). (f) Tragus broad with posterior margin smoothly convex; shape semi-lunate (e.g. *N. macrotis*). (g) Tragus narrow with posterior margin smoothly convex; shape not semi-lunate (e.g. *N. hispida*). (h) Tragus inverted pear-shaped with posterior margin deeply notched (e.g. *N. thebaica*). (i) Tragus with posterior margin concave or slightly concave (with 'kink' at centre) (e.g. *N. arge*; after Rosevear 1965). Left tragus illustrated; all drawn to same length.

Relative length of ear. In African species, ears range in relative length from 52–80% of FA, so 52–61% of FA is relatively short, 62–71% of FA is medium, and 72–80% of FA is relatively long.

Tib (length of tibia). In African species, mean length ranges from 15–30 mm, so 15–20 mm is comparatively short, 21–25 mm is medium, and 26–30 mm is comparatively long.

Relative length of tibia. In African species, mean relative length ranges from 44–56% of FA, so 44–48% is relatively short, 49–52% is medium and 53–56% is relatively long.

Shape of the baculum. The tip can be simple (Figure 94a–d), ventrally hooked (Figure 94e–h) or trifid (Figure 94i–k); for minor intra-specific variations, see Thomas *et al.* 1994.

Figure 94. Bacular morphology in *Nycteris*. Bacula tips simple: (a) *N. arge*, (b) *N. nana*, (c) *N. gambiensis* (specimen 1) and (d) *N. gambiensis* (specimen 2). Bacula tips ventrally hooked: (e) *N. hispida* (specimen 1), (f) *N. hispida* (specimen 2), (g) *N. hispida* (specimen 3) and (h) *N. grandis*. Bacula trifid-tipped: (i) *N. macrotis* (specimen 1), (j) *N. macrotis* (specimen 2) and (k) *N. macrotis* (specimen 3). For each species, left illustration is the dorsal view with tip uppermost; right illustration is the lateral view of the right side with tip uppermost. Bacula for up to three different specimens are included to indicate intra-specific variation. All bacula traced from Thomas *et al.* (1994).

Table 18. Key to the African species in the genus *Nycteris*. Forearm lengths for *N. arge*, *N. intermedia*, *N. major* and *N. nana* from J. Fahr (see profiles), all others from Van Cakenberghe & DeVree (1985, 1993, 1998).

| Upper incisors | Posterior lower premolar | Posterior margin of tragus (Tragus shape) | FA mean \pm 1 S.D. (mm) | E (mm) | Tib (mm) | Miscellaneous | Species |

(45–49) | 29.2
(27–31) | 26.3
(24–28) | Baculum: no data
Tibia 56 (53–59)% of FA
Concavity of tragus well defined | <i>N. major</i> |

^aThe taxonomic status of *N. vinsoni* is uncertain: the tragi of the only two specimens are damaged and their shape uncertain. If deeply notched and pear-shaped, the specific status is probably valid, but if smoothly convex and semi-lunate, *vinsoni* is probably as synonym of *N. macrotis* (see profile *N. vinsoni*).

Andersen (1912b) divided the African species of *Nycteris* (as *Petalia*) into four species-groups on the basis of morphological characters, including the size of the lower premolar, the shape of the upper incisors and the shape of the tragus. Using multivariate statistical analyses of morphological characters, Van Cakenberghe & De Vree (1985, 1993, 1998) confirmed that four African species-groups can be recognized. So too did Griffiths (1994) based on hyoid and other morphology. We follow the species and species-group compositions suggested by Van Cakenberghe & De Vree, with the exception that *N. parisi* is considered distinct from *N. woodi* on the basis of bacular morphology (Thomas *et al.* 1994) and the relative size of the ears (see profiles). The African species-groups, their characters and species are:

arge group. Posterior lower premolar large; upper incisors bicuspid; tragus with posterior margin concave. *N. arge*, *N. intermedia*, *N. major* and *N. nana*.

macrotis group. Posterior lower premolar small; upper incisors bicuspid; tragus semi-lunate, posterior margin smoothly convex. *N. macrotis*, *N. parisi* and *N. woodi*.

hispidia group. Posterior lower premolar small; upper incisors tricuspid; tragus not semi-lunate, posterior margin smoothly convex. *N. aurita*, *N. grandis* and *N. hispidia*.

thebaica group. Posterior lower premolar small; upper incisors bicuspid; tragus pear-shaped, posterior margin deeply notched. *N. gambiensis*, *N. thebaica* and ? *N. vinsoni*.

The species are presented in alphabetical order, irrespective of the species-group to which they belong.

Meredith Happold

Nycteris arge BATES'S SLIT-FACED BAT

Fr. Nyctère de Bates; Ger. Bates' Schlitznasen-Fledermaus

Nycteris arge Thomas, 1903. Ann. Mag. Nat. Hist., ser. 7, 12: 633. Efulen [= Efulan], SW Cameroon.

Taxonomy Species-group: *arge*. Synonyms: none. Some authors considered *N. intermedia* as a synonym. Chromosome number: not known.

Description Small to very small microbat with noseleaf comprised of a longitudinal cleft bordered by fleshy outgrowths; medium-small for a *Nycteris* (FA: 39–46 mm, GLS: 19.2–20.4 mm); upper incisors bicuspid; posterior lower premolar large; tragus with posterior margin slightly concave; E: 25–34 mm; Tib: 19–26 mm, 48–58% of FA. Not easily distinguished from *N. major*. Sexes similar. Pelage loose, fluffy; mid-dorsal hairs 9–10 mm. Dorsal pelage medium brown, rusty-brown or dark brown, sometimes straw-coloured on forehead between ears and along their outer margin. Ventral pelage similar but paler; some individuals with irregular whitish or pale brown patches. (One albino individual was found in Tâi N. P., Côte d'Ivoire; J. Fahr unpubl.) Ears broad, rounded, of medium length for a *Nycteris* and also of medium relative length (67 [60–79]% of FA); uniformly blackish-brown. Tragus with slight and ill-defined concavity ('kink') at centre of posterior margin (Figure 93i). Muzzle of naked appearance and pink. Wings and interfemoral membrane blackish-brown. Tibia of medium length for a *Nycteris* (22.0 [19–26] mm) and of medium relative length (52 [48–58]% of FA). Baculum tip simple (Figure 94a; Thomas *et al.* 1994).

Skull with sagittal crest low. Upper incisors bicuspid. Posterior lower premolar comparatively large (rising well above cingula of adjacent teeth and equal or almost equal to height of anterior cusp of first molar) and within toothrow.

Geographic Variation None.

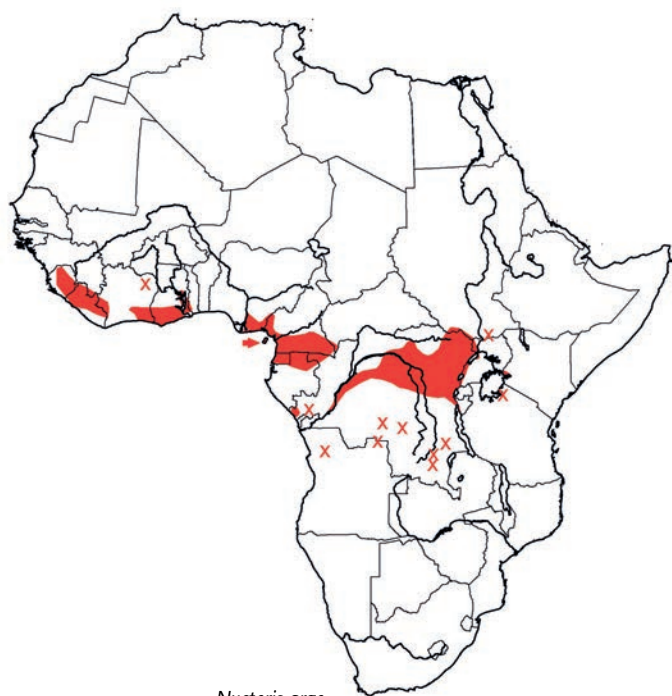

Similar Species Three other African *Nycteris* have the following combination of characters: upper incisors bicuspid; posterior lower premolar large; tragus with posterior margin concave (Table 18, p. 441):

Nycteris nana. Much smaller (FA: 32–37 mm; GLS: 15.6–17.0 mm). Tibia <47% of FA. Ears shorter (19–23 mm). Concavity in posterior margin of tragus well defined.

N. intermedia. Smaller (FA: 36–38 mm; GLS: 17.5–18.7 mm). Ears shorter (20–24 mm). Concavity in posterior margin of tragus well defined.

N. major. Almost always larger (FA: 47.5 ± 1.0 [45–49] mm; GLS: 21.0 [20.4–22.4] mm). According to Eisentraut (1956), the claws are broader, much stouter and blunter than in *N. arge*, but this was questioned by Rosevear (1965) and Van Cakenberghe & De Vree (1985). In some specimens there is overlap in univariate measurements between *N. arge* and *N. major*, and multivariate analysis is needed to distinguish between them (Van Cakenberghe & De Vree 1985).

Distribution Endemic to Africa. Mainly recorded from the Rainforest BZ (Western, West Central, East Central and South Central Regions) and the Rainforest–Savanna Mosaics. Frequently recorded, therefore gaps in the distribution are unlikely to reflect insufficient sampling in these areas. Recorded from Sierra Leone, Liberia, Côte d'Ivoire, Ghana, Togo, Nigeria, Cameroon, Equatorial Guinea (incl. Bioko I.), Gabon, Congo, DR Congo, Central African Republic, Sudan, Uganda, Burundi (Bururi F. R., Ruhinga Hill; FMNH), Kenya, Tanzania and Angola. Nigerian records from Afon and Kudu (Happold 1987) based on specimens in the USNM were probably misidentified – no specimens of *N. arge* from these localities are currently in the USNM and the habitat is not likely to be suitable. A record from Somalia (De Beaux 1923b) is based on misidentified specimens of *N. macrotis* (Koopman 1975). Based on their measurements, some of the specimens from Bioko I. published by Juste & Ibáñez (1994) as *N. arge* probably also include *N. intermedia* and *N. major* and should be re-examined.

Nycteris arge

Habitat Mainly recorded in lowland rainforest, coastal forest and forest–savanna mosaic, but also found in montane forest and swamp forest, and occasionally in or near relict forests and gallery forests in the Guinea Savanna BZ, and in *Acacia–Commiphora* bushland and miombo woodland. Most records are from undisturbed forests but this species is apparently able to cope with degraded and secondary forests and even cocoa plantations (e.g. Juste & Ibáñez 1994).

Abundance *Nycteris arge* is the most common species in the *N. arge* group and the most abundant nycterid in forest habitats.

Adaptations The preferred day-roosts are standing, hollow trees with an opening near the base of the trunk. Verschuren (1957) found this bat in Garamba N. P., NE DR Congo, in hollow trunks of *Alstonia congensis*, *Cordia* sp., *Hallea stipulosa*, *Klainedoxa gabonensis* and *Macaranga* sp. trees. Other day-roosts include fallen logs, small caves, culverts under roads, uninhabited buildings and a belfry. Day-roosts are sometimes shared with *Hipposideros cyclops* and *Rhinolophus landeri* (Lang & Chapin 1917b, Aellen 1952, Eisentraut 1956, 1973a, Rosevear 1965, Wolton *et al.* 1982, Juste & Ibáñez 1994).

Foraging and Food Forages by gleaning close to the ground in the understorey of the forest. In Côte d'Ivoire (Taï N. P. and Comoé N. P.), flight height (as determined by captures in mist-nets set 0–25 m above ground) was 0.7 (0.4–2.6) m ($n = 34$, J. Fahr unpubl.). Rosevear (1965) stated that these bats hunt mainly in clearings in forest but this could not be substantiated (J. Fahr pers. obs.). They glean from vegetation and probably also from the ground. Diet not known but likely to consist of rather soft-bodied arthropods.

Echolocation As in other nycterids, the echolocation calls consist of multiharmonic, steep FM sweeps, according to Novick (1958b) with 3–5 harmonics, a frequency range of 16–107 kHz and a call-duration of 0.4–1.4 ms. The sound is emitted through the nostrils.

Social and Reproductive Behaviour Roosts singly or in groups of 2–3 (rarely four) individuals. Groups are frequently composed of a pair with one young, and sometimes composed of two ♂♂ (Verschuren 1957, J. Fahr unpubl.).

Reproduction and Population Structure Litter-size: one. Reproductive chronology not known. In Côte d'Ivoire, pregnant ♀♀ were recorded in Mar (1 of 3), Sep (1 of 4) and Oct (1 of 1) (Taï N. P., 05° 50' N); Jul and Aug ($n = 2$) (Adiopodoumé: 05° 20' N) and May ($n = 1$) (Comoé N. P., 08° 45' N) (J. Fahr unpubl., MHNG). One lactating ♀ was found in May (Comoé N. P.) and another in late Aug (Ghana, near Anum: 06° 30' N), the latter with an attached juvenile 70 mm long (J. Fahr unpubl., USNM). These observations indicate that births are not restricted to one season per year, but as yet there is no evidence of polyoestry. Testis size varies in ♂♂ between 3.2×2.7 mm and 4.1×2.9 mm but the seasonal pattern is inconclusive. In Côte d'Ivoire, the ratio of ♂♂ to ♀♀ in marked bats captured in mist-nets set in standardized transects was 1 : 0.5 ($n = 33$) in Taï N. P., and 1 : 1 ($n = 10$) in Comoé N. P.

Predators, Parasites and Diseases Remains of one individual were found in the scats of an unidentified small carnivore in Dzanga-Sangha N. P., Central African Republic (Hutterer & Ray 1997). Ectoparasites include a bug *Eothenes nycteridis* (Hemiptera: Polyctenidae) and mites *Paraperiglischrus nycteris* (Acari: Spinturnicidae), *Nycterimyobia camerounensis* and *N. nycteris* (Acari: Myobiidae) (Anciaux de Faveaux 1984, Uchikawa 1988).

Conservation IUCN Category: Least Concern.

Nycteris aurita ANDERSEN'S SLIT-FACED BAT

Fr. Nyctère à longues oreilles; Ger. Andersens Schlitznasen-Fledermaus

Nycteris aurita (K. Andersen, 1912). Ann. Mag. Nat. Hist., ser. 8, 10: 547. Kitui, Kenya.

Taxonomy Originally: *Petalia aurita*. Species-group: *hispidia*. Synonyms: none. Considered a synonym or subspecies of *N. hispidia* by several authors including Harrison (1957b), Kock (1969a) and Ansell (1978), but considered to be a distinct species by Koopman (1975) and (on the basis of multivariate analysis of skull measurements) by Van Cakenberghe & De Vree (1993). Although Koopman (1994) listed *aurita* as a subspecies of *N. hispidia*, he remarked that both *aurita* and *hispidia* occur in E Kenya and 'may act as separate species'. Chromosome number: not known.

Description Small to very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-small for a *Nycteris* (FA: 37–45 mm); upper incisors tricuspid, posterior lower premolar small, posterior margin of tragus smoothly convex; E: 25–31 mm; Tib: 18–22 mm, 51 (48–54)% of FA. Sexes similar. Pelage of medium length, loose and fluffy. Dorsal pelage usually dark beige to dark brown, sometimes paler; hairs unicoloured or with central portion paler. Ventral pelage paler. Ears of medium length for a *Nycteris* and of medium relative length (62 [52–71]% of FA). Tragus narrow (not semi-lunate), posterior margin smoothly convex without notch (as in *N. hispidia*; Figure 93g). Eyes minute. Wings and interfemoral membrane blackish-brown. Hindlimbs long and slender; soles, toes and claws very small. Tibia of medium length for a *Nycteris* (20.3 [18–22] mm) and of medium relative length (49 [46–53]% of FA). Bacular morphology not known.

Skull with sagittal crest very low or absent. Upper incisors tricuspid. Posterior lower premolar small (not reaching height of anterior cusp on first molar), within toothrow.

Geographic Variation None recorded. If the distribution is as restricted as current records indicate, geographic variation is unlikely.

Similar Species Only two other African *Nycteris* have tricuspid upper incisors (Table 18, p. 441):

Nycteris hispidia. Ears smaller (16–24 mm), other measurements on average smaller (FA: 38.7 ± 1.65 mm; GLS: 16.5 [15.3–18.4] mm; C–M³: 5.3 [4.6–6.7] mm; M³–M³: 5.9 [5.1–7.6] mm; C–M₃: 5.9 [5.1–7.6] mm). Best distinguished from *N. hispidia* by multivariate analysis of skull measurements (Van Cakenberghe & De Vree 1993).

N. grandis. Much larger (FA: 52–65 mm; GLS: 23.3–27.5 mm).

Distribution Endemic to Africa. Most records are from the Somalia–Masai Bushland BZ, but the geographic range extends marginally into the Sudan Savanna and Zambezian Woodland BZs. Recorded from Ethiopia, Somalia, Kenya and Tanzania. Specimens from Zambia and DR Congo, referred to as *N. h. aurita* by Ansell (1978), are considered to represent *N. hispidia* by Van Cakenberghe & De Vree (1993).

*Nycteris aurita*

Habitat Most localities appear to be in *Acacia–Commiphora* deciduous bushland and thicket, sometimes near rivers and riverine forests. Recorded, in Tanzania, from two coastal forests (Ruvu South and Somanga) (Cockle *et al.* 1998), from a coconut plantation at Msala, and from a thatched house in grassland near coastal mangroves on Ras Dima I. (Eisentraut 1958). Probably often occurs in more arid habitats than *N. hispidia*.

Abundance Uncertain.

Remarks Very little appears to be known about this species. Some information recorded for *N. hispidia* might pertain to *N. aurita* (e.g. Kingdon 1974). Matthews (1941) examined 12 individuals collected at ca. 4°S in Tanzania in late Dec: they included two lactating ♀♀, one non-lactating parous ♀ showing signs of approaching oestrus, and three 'sexually active' ♂♂. Although Matthews referred to these as *N. hispidia*, the length of their ears indicates that they probably represent *N. aurita*. Also, at ca. 8°S in Tanzania, a lactating ♀ was recorded in early May (Ras Dima I.) and a subadult in mid-Apr (Msala) (Eisentraut 1958).

Conservation IUCN Category: Least Concern.

Population trend not known.

Nycteris gambiensis GAMBIAN SLIT-FACED BAT

Fr. Nyctère de Gambie; Ger. Gambia Schlitznasen-Fledermaus

Nycteris gambiensis (K. Andersen, 1912). Ann. Mag. Nat. Hist., ser. 8, 10: 548. Dialakoto, Senegal.

Taxonomy Originally *Petalia gambiensis*. Species-group: *thebaica*. Synonyms: none. Considered a subspecies of *N. thebaica* by Aellen (1956b), Kock (1969a) and Koopman (1975), but given specific status by Adam & Hubert (1976), Koopman (1993, 1994) and Van Cakenberghe & De Vree (1998). Chromosome number: not known.

Description Small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-small for a *Nycteris*; upper incisors bicuspid; posterior lower premolar small; tragus pear-shaped with posterior margin deeply notched; FA: 40.15 ± 1.44 (35–44) mm; E: 24–30 mm; Tib: 19.87 ± 0.99 (17–22) mm, 48.9 (46–53)% of FA; GLS: 17.58 ± 0.36 mm (mean \pm 1 S.D.). Not easily distinguished from *N. thebaica* but *N. gambiensis* is on average smaller than *N. thebaica* from West Africa where the two species are sympatric (see Similar Species). Sexes similar. Pelage loose and fluffy; mid-dorsal hairs 9–10 mm. Dorsal pelage dark beige, greyish-brown or sepia brown; hairs unicoloured or with basal half darker than terminal half. Ventral pelage slightly paler than dorsal pelage (cf. *N. thebaica*); hairs sepia brown with paler tips. Ears of medium length for a *Nycteris* and of medium relative length (67 [61–71]% of FA). Tragus inverted pear-shaped with notch in posterior margin (similar to *N. thebaica*, Figure 93h). Eyes minute. Wings blackish-brown; interfemoral membrane brown. Tibia short for a *Nycteris* but of medium relative length (49 [42–53]% of FA). Baculum tip simple (Figure 94c and d; Thomas *et al.* 1994).

Skull with sagittal crest very low. Upper incisors bicuspid. Posterior lower premolar minute (not rising above cingula of adjacent teeth and sometimes not visible above gum), displaced lingually to a greater or lesser extent; anterior premolar in contact with first molar or nearly so (cf. *N. thebaica*).

Geographic Variation None recorded.

Similar Species Only one other African *Nycteris* has the following combination of characters: upper incisors bicuspid; posterior lower premolar small; tragus (without doubt) pear-shaped with posterior margin deeply notched (Table 18, p. 441):

Nycteris thebaica. Ventral pelage paler to much paler than dorsal pelage.

In West Africa, on average larger (FA: 43.98 ± 1.31 mm; Tib:

Nycteris gambiensis

22.24 ± 1.06 mm; GLS: 18.68 ± 0.43 mm) (Van Cakenberghe & De Vree 1998). Anterior upper premolar and first molar usually separated by pronounced gap.

Nycteris vinsoni, if proved to have a pear-shaped tragus with a notch in the posterior margin, is probably a valid species (see profile) that also resembles *N. gambiensis* but it is probably larger (FA: 51 mm).

Distribution Endemic to Africa. Mainly recorded from the Sudan Savanna and Guinea Savanna BZs, but also recorded from the Northern Rainforest–Savanna Mosaic and Rainforest BZ. Distributed somewhat disjunctly from Senegal to W Nigeria, with one specimen from Cameroon (Van Cakenberghe & De Vree 1998). The apparent gaps in the distribution are unexplained: possibly they are artefacts resulting from inconsistent collecting.

Habitat Mainly found in undifferentiated woodland and *Isoperlinia* woodland, but with some records from (or near) grasslands and cleared areas in the Rainforest BZ (Grubb *et al.* 1998).

Abundance Uncertain: moderately common in collections.

Remarks By day, has been found roosting in a hollow tree, caves, derelict buildings, traditional houses and huts, and in roofs (Rosevear 1965, Grubb *et al.* 1998). A colony of ca. 50 occupied clefts in one cave in Guinea (Eisentraut & Knorr 1957). Lagos Bat virus has been isolated from this bat (Calisher *et al.* 2006).

Conservation IUCN Category: Least Concern.

Nycteris grandis LARGE SLIT-FACED BAT

Fr. Grande nyctère; Ger. Große Schlitznasen-Fledermaus

Nycteris grandis Peters, 1865. Monatsber. K. Preuss. Akad. Wiss. Berlin 1865: 358. 'Guinea'.

Taxonomy Species-group: *hispidus*. Synonyms: *baikii*, *marica*, *proxima*. Subspecies: none recognized by Van Cakenberghe & De Vree (1993), but see Geographic Variation. Chromosome number: not known.

Description Small to medium-sized microbat with noseleaf (longitudinal slit bordered by fleshy outgrowths); the largest *Nycteris* (FA: 52–65 mm); upper incisors tricuspid. Sexes similar. Pelage loose and fluffy; mid-dorsal hairs 11–12 mm. Dorsal pelage ranging from dark brown to reddish-brown (in forests) to greyish-brown or dark beige (in savannas); hairs paler at base. Ventral pelage slightly paler. Ears large for a *Nycteris* (24–35 mm), but relatively short (52 [46–59]% of FA). Tragus very narrow, not semi-lunate; posterior margin smoothly convex without notch (similar to *N. hispidus*, Figure 93g). Eyes minute. Wings and interfemoral membrane blackish-brown. Tibia long for a *Nycteris* and also relatively long (53 [49–55]% of FA). Baculum tip ventrally hooked (Figure 94h) (Thomas *et al.* 1994).

Skull (Figure 92) with sagittal crest well developed (see photographs in Hickey & Dunlop 2000). Upper incisors tricuspid. Posterior premolar small (usually rising just above cingula of adjacent teeth but well below height of anterior cusp on first molar) and within toothrow; anterior premolar and first molar well separated.

Geographic Variation Morphometrically, *N. grandis* is uniform throughout its geographic range and therefore no subspecies are recognized by Van Cakenberghe & De Vree (1993). However, this species has a disjunct distribution with darker and usually solitary individuals in rainforest habitats, and paler usually group-living individuals in savanna habitats (Tanzania, Zambia, Malawi and Zimbabwe). The latter possibly, but not necessarily, represent another subspecies, *N. g. marica* (Ansell 1978, Kock 1981). (For similar scenario, see *N. macrotis*.)

Similar Species Only two other African *Nycteris* have tricuspid upper incisors (Table 18, p. 441):

Nycteris aurita. Much smaller (FA: 37–45 mm).

N. hispidus. Much smaller (FA: 33–44 mm).

Distribution Endemic to Africa. Mainly recorded from the Rainforest BZ (and marginally from the Rainforest–Savanna Mosaics) from Senegal to NE DR Congo, with a seemingly separate population

Nycteris grandis

in the Coastal Forest Mosaic BZ of Kenya, Tanzania, Pemba I. and Zanzibar I., and scattered populations in the Zambezian Woodland BZ in Zambia, Malawi, Zimbabwe and Mozambique. Map based on Van Cakenberghe & De Vree (1993). Recently, a specimen from Gashora in SE Rwanda (02° 11'S, 30° 14'E) was published by Kityo *et al.* (2009); this first record from Rwanda has not been mapped.

Habitat In West and central Africa, predominantly rainforest habitats including swamp forest and secondary forest, with some records in dense humid riverine and relict forests outside the rainforest zone. In East Africa, known only in the coastal forests. In south-central Africa and southern Africa, seemingly isolated populations have been found in woodlands (including miombo and *Acacia albida* woodlands) and riverine forests, in the vicinity of large rivers such as the Zambezi, Luangwa, Shire and Buzi. Often found where there are baobabs *Adansonia*; these trees often have large hollow trunks in which *N. grandis* roosts.

Abundance Uncertain. Only moderately common in collections, but these bats are difficult to find, detect and capture.

Adaptations Aspect ratio very low; wing-loading low. Can take off from the ground, can almost hover, turns by banking (minimum radius <25 cm) and by stalling-and-twisting. Individuals sustained flight within a 1×1×1 m enclosure for up to seven circuits/flight (4 bats, 10 flights each; M. Happold unpubl.). Often reported roosting by day, hanging apart, in large hollows within standing trees (including baobabs, *Mitragyna stipulosa*, *Ceiba pentandra* and *Acacia albida*); occasionally found roosting in hollow logs, holes in ground and between rocks, and similar man-made sites such as dark abandoned rooms, water towers, culverts and mine-adits (Verschuren 1957, Rosevear 1965, Brosset 1966, Adam & Hubert 1976, Fenton *et al.* 1990, Happold & Happold 1997). One adult ♀ was collected from a flower of *Kigelia africana* (Kityo *et al.* 2009). Emerges between 19:00h and 21:00h; individuals vary from day to day (Fenton *et al.* 1990). Roost-fidelity has been observed and is probably normal; disturbed roosts may be abandoned but sometimes the occupants return after a few days. Does not become torpid by day under natural temperature regimes. Predicted mean maximum urine concentration is comparatively very low (2581 mOsmol/kg) (Happold & Happold 1988), implying that this species is highly dependent on water for drinking. Bats in captivity for four days did not drink but might have died of dehydration if kept longer. Fenton *et al.* (1983) kept seven in captivity, on a natural diet, but all died between 8–17 days; it was not reported whether they drank or not.

Foraging and Food Feeds on flying and non-flying insects and other arthropods, and small vertebrates including frogs, fish, birds and small bats; its diet and foraging have been well studied (Fenton *et al.* 1981, 1983, 1987, 1990, 1993). Forages by slow-hawking and perch-hunting (including both fly-catching and ground-gleaning), usually close to the ground, in forests, near edges of clearings, woodlands, over streams, rivers and marshes, and near lights where flying insects have aggregated. While perch-hunting, hangs from the perch by one foot and scans the surroundings by rotating the body through 180 degrees, elevating and twisting the head, and tilting the ears to and fro. Prey is detected by echolocation, and also by prey-generated

sounds including the low-frequency sounds of fluttering insects and prey moving on the ground, and the low frequency vocalizations of bats. Does not respond to the echolocation calls of bats, the calls of male frogs, or to prey that is silent and immobile. Captive individuals respond to chewing sounds made by conspecifics, and often attempt to steal their food. When perch-hunting, *N. grandis* swoops down on prey on the ground, envelopes it in the wings and immobilizes it by biting the head. Flying insects and bats are tracked and intercepted (not followed from behind), grasped in the mouth and immobilized by biting the head. Prey is carried to the perch where it is eaten slowly, sometimes as much as an hour later. Uses its wings to position the prey; frogs and bats are cupped in the wrist area of one wing and held to the mouth. Legs of insects and frogs, wings of moths and bats, skin and fur are discarded. Small bones are chewed and swallowed. Capture of fish has apparently not been observed, but Smithers (1983) suggests that stranded fish might be taken from drying pools.

Nycteris grandis is the only African bat that routinely feeds on small vertebrates as well as insects and other arthropods. Remains of arthropod prey, under feeding-perches in Zimbabwe, included Lepidoptera (moths), Orthoptera (katydids, grasshoppers, locusts, praying mantids), Coleoptera (beetles), Neuroptera (lace-wings, ant-lions) and Solifugidae (camel spiders, sun spiders). Remains of small vertebrates included small bats (at least six species including nycterids, rhinolophids, hipposiderids and vespertilionids), birds, frogs (seven species) and fish (three species). Captive bats also ate skinned mice (Happold & Happold 1988). In the wild, small vertebrates comprised ca. 80% of the diet by weight. Frogs were the most common prey (total numbers) in Mar–May, Aug and Sep; bats in Jun–Jul; and arthropods in Dec–Feb. As well as seasonal changes, diets varied from year to year, suggesting opportunism albeit with preferences for some foods. Captive bats preferred katydids and beetles to moths.

Echolocation Early approach-phase echolocation calls are short (1 ms or less), low intensity, multiharmonic calls with a complex overlay of harmonics, 17–104 kHz. Later, when the prey is closer, the calls become less complex and much narrower in bandwidth and, when prey is attacked, the calls become steep FM sweeps from 110 to 61 kHz. Call repetition-rate increases dramatically as prey is approached and attacked (Fenton *et al.* 1983).

Social and Reproductive Behaviour In the rainforest zone, 'seems to be solitary except at breeding times' (Rosevear 1965). In Zimbabwe, Malawi and Zambia, it has been found roosting singly, in twos and in small groups. Adults do not roost in contact with each other. Young are left in the day-roost while mothers forage, and mothers often use their day-roosts as feeding-perches at this time (Fenton *et al.* 1987). Records of occupants of day-roosts include (a) 1 adult ♂, (b) 2 post-lactating ♀♀, 1 subadult ♀, 4 others, (c) 5 ♀♀ with young and 1 reproductively inactive ♀, (d) 2 ♀♀ with young, (e) 1 adult ♂, 2 lactating ♀♀ and their young, (f) 1 adult ♂ and 7 pregnant ♀♀ (Ansell 1986b, Fenton *et al.* 1987, M. Happold unpubl.).

Reproduction and Population Structure Litter-size: one (n = 10) (Brosset 1966, Verschuren 1976, Ansell 1986b). Reproductive chronology not known (no year-round data from any one locality). At 7–8°N (Mt Nimba, Liberia), a single ♀ had a 5 mm embryo in Dec (Verschuren 1976), and lactating ♀♀ were recorded

in Jul and Aug (Wolton *et al.* 1982). At 0–1° N (Bélinga-Makokou, Gabon), newborn young (n = 3) were recorded in Apr and Aug, and a ♀ with large foetus in Nov (Brosset 1966). At 13° S in Zambia, 8 of 8 ♀♀ had large fetuses (CR: 20–27 mm) in mid-Sep (Ansell 1986b). At 15° S (Liwonde N. P., Malawi), 2 of 2 ♀♀ were lactating in Mar, and 2 of 2 were post-lactating in Jun. At ca. 16° S (Mana Pools N. P., Zimbabwe), 4 of 5 ♀♀ had 1–7 days old young in early Dec; the other was neither pregnant nor lactating (Fenton *et al.* 1987).

Predators, Parasites and Diseases Ectoparasites include a bug *Eothenes nycteridis* (Hemiptera: Polyctenidae); a flea *Echidnophaga aethiops* (Siphonaptera: Pulicidae); and a mite *Alabidocarpus nycteris* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Nycteris hispida HAIRY SLIT-FACED BAT

Fr. Nyctère hérissé; Ger. Gemeine Schlitznasen-Fledermaus

Nycteris hispida (Schreber, 1775). Die Säugethiere 1: 169, 188. Senegal.

Taxonomy Originally *Vespertilio hispidus*. Species-group: *hispida*. Synonyms: *daubentoni*, *martini*, *pallida*, *pilosa*, *poensis* and *villosa*. *Nycteris aurita*, sometimes considered a subspecies of *N. hispida*, is considered here to be a distinct species following Van Cakenberghe & De Vree (1993). Chromosome number (Somalia): 2n = 42; aFN = 78 (Lee *et al.* 1989).

Description Small to very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; one of the five smallest and most gracile species of *Nycteris* (FA: 34–44 mm); upper incisors tricuspid; posterior lower premolar small; posterior margin of tragus smoothly convex; E: 16–24 mm; Tib: 14–24 mm, 46.2 (36–56)% of FA. Sexes similar in colour; ♀♀ slightly larger on average than ♂♂. Pelage loose and fluffy; mid-dorsal hairs ca. 10 mm. Dorsal pelage variable: uniformly dark beige, greyish-brown or sepia brown; hairs unicoloured or with central portion paler. Ventral pelage paler to markedly paler than dorsal pelage; hairs darker at base. Ears short for a *Nycteris* and also relatively short (58 [50–71]% of FA). Tragus (Figure 93g) narrow (not semi-lunate); posterior margin smoothly convex without notch, upper margin rounded (cf. flattened in *N. woodi*). Eyes minute. Wings and interfemoral membrane blackish-brown. Tibia short for a *Nycteris* and also relatively short (46 [36–56]% of FA). Baculum tip ventrally hooked (Figure 94e, f and g) (Thomas *et al.* 1994).

Skull with sagittal crest very low or absent. Upper incisors tricuspid. Posterior lower premolar small (sometimes rising just above cingula of adjacent teeth but well below height of anterior cusp on first molar) and within tooththrow; anterior premolar and first molar well separated.

Geographic Variation Koopman (1994) considers *villosa* to be a valid subspecies, but Van Cakenberghe & De Vree (1993) found *N. hispida* to be very uniform throughout its entire geographic range.

Similar Species Only two other African *Nycteris* have tricuspid upper incisors (Table 18, p. 441):

Nycteris aurita. Ears larger (24–31 mm), other measurements on average larger (FA: 41.6 ± 1.72 mm; GLS: 17.9 [17.2–18.3] mm; C–M³ (alv.): 5.9 [5.7–6.2] mm, M³–M³: 6.79 [6.2–7.2] mm; C–M₃ (alv.): 6.7 [6.4–7.5] mm). Best distinguished from *N. aurita* by multivariate analysis of skull measurements (Van Cakenberghe & De Vree 1993).

N. grandis: much larger (FA: 52–65 mm; GLS: 23.3–27.5 mm).

If the upper incisors are worn, *N. hispida* can be confused with *N. woodi* but, in the latter, the upper margin of the tragus is flattened (cf. rounded in *N. hispida*).

Distribution Endemic to Africa. Widely distributed in the Sudan and Guinea Savanna BZs (and marginally in Sahel Savanna Zone) and in the Rainforest BZ, Rainforest–Savanna Mosaics, Somalia–Masai Bushland BZ, Afromontane–Afroalpine BZ, Coastal Forest Mosaic BZ and Zambezian Woodland BZ. Recorded from Mauritania to Sudan, Ethiopia and Somalia, and southwards to Angola, Botswana and KwaZulu–Natal in South Africa. Also Bioko I. and Zanzibar I. Records from Cape of Good Hope are probably erroneous (Cotterill 1996a). Map based on Van Cakenberghe & De Vree (1993).

Habitat Can exploit a wide range of vegetation types, possibly because its roosting habits are comparatively unspecialized (Rosevear 1965). These include undifferentiated woodland and *Isobertinia* woodland, lowland rainforest and rainforest–savanna mosaics, miombo woodland and drier woodlands. Probably avoids grassland, montane and semi-arid habitats.

Nycteris hispida

Abundance Very common north of 10°S. One of the most common nycterids.

Adaptations Aspect ratio very low; wing-loading very low; wing-tip very rounded (M. Happold unpubl.). Flies slowly with very great manoeuvrability. Can take off from the ground, can hover briefly, turns by banking (minimum radius <25 cm) and by stalling-and-twisting. Individuals sustained flight within a 1×1×1 m enclosure for up to 93 circuits/flight (3 bats, 10 flights each; M. Happold unpubl.). Well known for its ability to dodge objects, moving and otherwise: rarely caught in mist-nets and extremely difficult to catch in butterfly nets, even if confined in small rooms (e.g. Lang & Chapin 1917b). By day, hangs freely from twigs of low bushes and trees, always in dense cover and complete shade (Verschuren 1957, Rosevear 1965). Also hangs under open banana leaves, from ridge-poles of grass- or mat-roofed houses, in hollow trees, dark cavities under exposed roots of trees in erosion gullies and ravines, disused huts, burrows (? Aardvark burrows), caves, road culverts, deep holes in the ground and in termitaria (Verschuren 1957, Rosevear 1965, Brosset 1966, Kock 1969a, Smithers & Wilson 1979, Kityo & Kerbis 1996, Grubb *et al.* 1998). In the Okavango Swamp, Botswana, roosts in dense beds of papyrus *Cyperus papyrus* (Archer 1977).

Foraging and Food Feeds on small moths and other insects (including praying mantises), which are caught by slow-hawking and gleaning from foliage and walls (and probably from the ground). In the Okavango Swamp, foraged along narrow channels through papyrus (Archer 1977). Often attracted to lighted rooms and verandas, and other lights, where insects are abundant, and sometimes returns regularly to such places (e.g. Grubb *et al.* 1998).

Social and Reproductive Behaviour Often found roosting singly, and less often in pairs and groups of 3–6. In Garamba N. P.,

NE DR Congo, Verschuren (1957) frequently observed pairs, and family groups comprised of an adult ♂ and ♀, a juvenile and a reproductively inactive adult. He also observed ca. 20 individuals in an extended patch of vegetation near the Garamba R. but it is not clear if this was one social unit or several separate small groups. In the Okavango, normally seen foraging singly; three seen together on one occasion (Archer 1977).

Reproduction and Population Structure Litter-size: one. Reproductive chronology uncertain. At ca. 4°N (Garamba N. P., NE DR Congo) Verschuren (1957) collected 2–6 ♀/month from Jan–Jul in 1951 and 1952: reproductively active ♀♀ were in synchrony with pregnancies in Jan–Mar, births in Apr and lactation until late Jun. The percentage of captured ♀♀ which were breeding in 1951 was 100%, and 84% in 1952. Verschuren (1957) also recorded one birth in Sep 1951, and one lactating ♀ in Nov 1951, but he obtained no other data for Aug–Dec 1951. The data are consistent with seasonal bimodal polyoestry. Furthermore, at 03°22'S (Mto-wa-mbo, Tanzania), Matthews (1941) reported signs of approaching oestrus in one recently lactating ♀ in Dec, and suggested ♀♀ have two litters/year with no overlap of pregnancy and lactation. Data from elsewhere are fragmentary and inconclusive. Neonates are naked; FA: ca. 15 mm. Carried by mother until at least half-grown. Reach adult-size in less than two months.

Predators, Parasites and Diseases Predators include a tree snake *Boiga blandingii* (Jones 1961). Ectoparasites include a flea *Lagaropsyllida idae* (Siphonaptera: Ischnopsyllidae); a bat-fly *Raymondia alulata* (Diptera: Streblidae); a tick *Amblyomma nuttalli* (Acari: Ixodidae); and ten species of mites (Acari: Macronyssidae, Demodicidae, Myobiidae, Trombiculidae, Erythetidae, Psorergatidae, Chirodiscidae, Gastronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Nycteris intermedia INTERMEDIATE SLIT-FACED BAT

Fr. Nyctère d'Aellen; Ger. Intermediäre Schlitznasen-Fledermaus

Nycteris intermedia Aellen, 1959. Archs. Sci. Genève 12: 218: Adiopodoumé, ca. 15 km WNW of Abidjan, Côte d'Ivoire.

Taxonomy Species-group: *arge*. Synonyms: none. Considered a synonym of *N. arge* by some authors (e.g. Rosevear 1965, Hayman & Hill 1971) but Eisentraut (1973a) and Van Cakenberghe & De Vree (1985) confirmed the species rank attributed by Aellen (1959). Chromosome number: not known.

Description Very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; one of the smallest and most gracile species of *Nycteris* (FA: 36–38 mm, GLS: 17.5–18.7); upper incisors bicuspid; posterior lower premolar large; tragus with marked concavity ('kink') in posterior margin; E: 20–24 mm; Tib: 18–21 mm, 50–58% of FA. Pelage loose and fluffy; mid-dorsal hairs ca. 9 mm. Dorsal pelage variable: medium brown, rusty-brown, reddish-brown to dark brown. Ventral pelage similar but paler. Ears broad and rounded, short for a *Nycteris* but of medium relative length, 63 (60–66)% of FA; dark brown or blackish with the basal third of the inner side much paler. Tragus with a well-defined concavity ('kink') at centre of posterior margin. Muzzle of naked appearance and pink. Wing-membranes dark brown or blackish-brown. Tibia comparatively short for a *Nycteris* but relatively long (54 [50–58]% of FA). Bacular morphology not known.

Upper incisors bicuspid. Posterior lower premolar comparatively large (rising well above cingula of adjacent teeth and equal or almost equal to height of anterior cusp of the first molar) and within toothrow.

Geographic Variation None.

Similar Species Three other African *Nycteris* have the following combination of characters: upper incisors bicuspid; posterior lower premolar large; tragus with posterior margin concave (Table 18, p. 441):

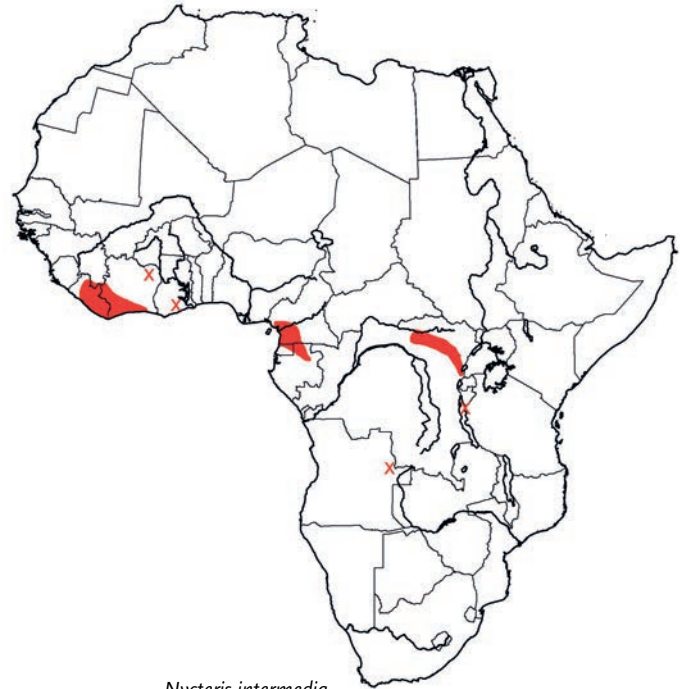

Nycteris nana. Smaller (FA: 32–37 mm; GLS: 15.6–17.0 mm). Tibia <47% of FA.

N. arge. Larger (FA: 39–46 mm; GLS: 19.2–20.4 mm). Ears comparatively longer, 25–34 mm. Concavity in posterior margin of tragus poorly defined.

N. major. Much larger (FA: 45–49 mm; GLS: 20.4–22.4 mm).

Distribution Endemic to Africa. Mainly recorded from the Rainforest BZ (Western, West Central, East Central and South Central Regions) and adjacent Rainforest–Savanna Mosaics, with two isolated records from the Zambezian Woodland BZ. Known from 27 localities in Guinea (Ziéla, Mt Nimba; MNHN), Liberia, Côte d'Ivoire, Ghana, Cameroon, Gabon (Brosset 1966 as *N. nana*), DR Congo, Tanzania (Howell & Wrangham 1974 as *N. nana*) and Angola.

Habitat Mainly recorded from lowland rainforest and coastal forest vegetation zones. Also recorded from Albert N. P., DR Congo,

*Nycteris intermedia*

which is situated in a transition zone between forest–savanna mosaic and the montane forests flanking the Albertine Rift, and from two localities in miombo woodland (Lucano, Angola; Gombe Stream N. P., Tanzania). The habitat at Gombe Stream N. P. was described as mixed deciduous woodland near gallery forest (Howell & Wrangham 1974). Where gallery and relict forests provide suitable habitat, these bats also penetrate into the southern Sudan savanna (Comoé N. P., Côte d'Ivoire).

Abundance Uncertain but appears to be quite rare. Within the *arge* species-group, rarer than *N. nana* and *N. arge* but more common than *N. major*.

Adaptations Day-roosts have rarely been reported. One bat was found in a cave leading vertically into the ground, another in an abandoned house (Brosset 1966 as *N. nana*; Eisentraut 1973a).

Foraging and Food Forages, by gleaning, close to the ground in the understorey of the forest. In Tai N. P. and Comoé N. P. (Côte d'Ivoire), the flight height (as determined by captures in mist-nets set 0–25 m above ground) was 1.4 (1.1–1.9) m, $n = 3$ (J. Fahr unpubl.). Sometimes flies into lighted rooms (Howell & Wrangham 1974). Probably gleans insects from the vegetation and probably also from the ground. Diet not known but likely to consist of rather soft-bodied arthropods.

Social and Reproductive Behaviour A pair was reported from an abandoned house in Gabon (Brosset 1966).

Reproduction and Population Structure Litter-size: not known but probably one. Reproductive chronology not known. At 05° 50' N (Taï N. P., Côte d'Ivoire) a pregnant ♀ was caught in early Mar. Two ♂♂ from Taï N. P. and Comoé N. P. (08° 45' N), caught in Aug and May respectively, had scrotal testes.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

Much more restricted to true rainforest than is *N. arge* and threatened by habitat loss in known localities.

Jakob Fahr

Nycteris macrotis LARGE-EARED SLIT-FACED BAT

Fr. Nyctère de Dobson; Ger. Großohrige Schlitznasen-Fledermaus

Nycteris macrotis Dobson, 1876. Monogr. Asiat. Chiroptera, p. 80. Sierra Leone.

Taxonomy Species-group: *macrotis*. Synonyms: *aethiopica*, *aurantiaca*, *guineensis*, *luteola*, *oriana*. Previously included *madagascariensis* as a synonym, but Peterson *et al.* (1995) consider this Madagascan form to be a distinct species. Hayman & Hill (1971) tentatively suggested that *aethiopica* (including *luteola*) might be a distinct species, but this view is not accepted by most authors, including Van Cakenberghe & De Vree (1985) and Simmons (2005). Sometimes considered to include *N. vinsoni* (but see species profile). Subspecies: uncertain (see Geographic Variation). Chromosome number (Somalia): 2n = 40; aFN = 74; this karyotype is unique for nycterids as a result of a chromosomal translocation involving the largest autosome (Lee *et al.* 1989).

Description Small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-sized for a *Nycteris*; upper incisors bicuspid, posterior lower premolar small; tragus semi-lunate with posterior margin smoothly convex, usually larger than other species in the *macrotis* group (FA: 48.2 ± 2.03 [40–55] mm). Sexes similar in colour; ♀♀ on average slightly larger than ♂♂. Pelage loose, fluffy; mid-dorsal hairs 9–12 mm. Dorsal pelage (grey-phase) sepia brown, reddish-brown, brownish-grey to grey; hairs with basal half paler than terminal half. Ventral pelage paler; most often pale grey. Orange-phase: dorsal pelage brownish-orange to bright orange; some grey-phase individuals exhibit an infusion of orange or rufous in the brownish pelage, especially on head and around neck. Ears long for a *Nycteris* but of medium relative length (65 [54–80]% of FA, n = 62). Tragus semi-lunate (half-moon shaped) with posterior margin smoothly convex (Figure 93f). Eyes small. Wings and interfemoral membrane greyish-brown to dark grey. Tibia of medium length for a *Nycteris* but relatively short (47 [37–53]% of FA). Baculum comparatively very long (3.84–5.12 mm); shaft long, parallel-sided, usually straight, thickening towards base; base with two basal lobes of varying development, in lateral view sometimes angled ventrally; tip expanded and trifold (Figure 94i, j and k; Thomas *et al.* 1994).

Skull with sagittal crest low but sharply defined anteriorly, absent posteriorly. Upper incisors bicuspid. Posterior lower premolar very small (not reaching above cingula of adjacent teeth), within toothrow or slightly displaced lingually.

Geographic Variation Uncertain. Van Cakenberghe & De Vree (1985) do not recognize any subspecies. In contrast, four African subspecies are recognized by Koopman (1994) and Simmons (2005):

N. m. macrotis: mainly in forest habitats from Gambia to Uganda and southwards to N Angola and S DR Congo.

N. m. aethiopica: mainly in savanna habitats from Senegal to Ethiopia.

N. m. luteola: NE DR Congo and S Somalia to Tanzania, including Zanzibar I.

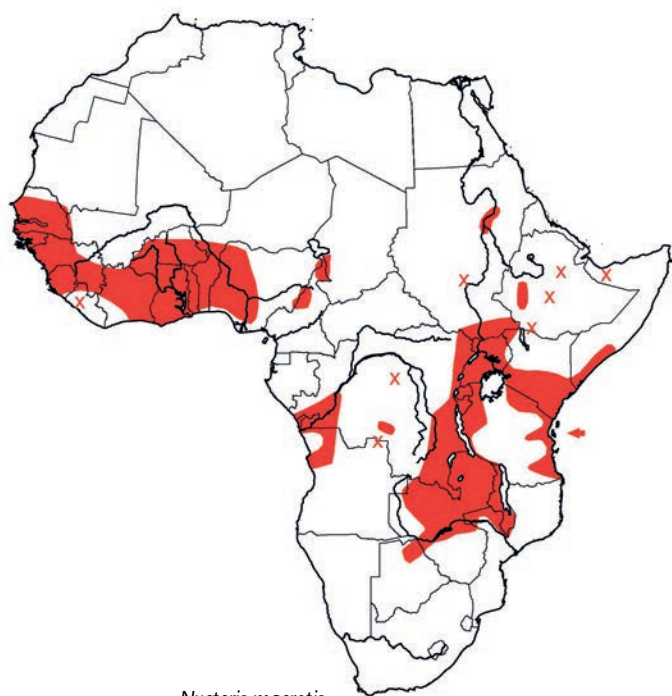

N. m. oriana: Tanzania, Malawi, Zambia, Zimbabwe.

Alternatively, it is possible that there are only two valid subspecies: *N. m. macrotis* in the Rainforest Zone and *N. m. aethiopica* (including *luteola* and *oriana*) in the savanna zones. It is also plausible that variation in *N. macrotis* is attributable solely to climate-related differences between forest and savanna habitats, and that subspeciation has not occurred at all (for a similar scenario, see *N. grandis*). Clearly, a pan-African investigation, using both morphological and genetic characters, is needed to elucidate the status of these forms.

Similar Species Only two other African *Nycteris* have the following combination of characters: upper incisors bicuspid; lower posterior premolar small; tragus with posterior margin convex (Table 18, p. 441):

Nycteris parisii. Usually smaller (FA: 40.0 [38–41] mm, n = 3).

Ventral pelage dark grey in the very few specimens for which there is information.

*Nycteris macrotis*

N. woodi. Usually smaller and less robustly built (FA: 39.3 ± 1.9 [36–42] mm). Ears usually relatively longer (79.5 [74–89]% of FA). Baculum tip simple and unexpanded.

Distribution Endemic to Africa. Recorded, disjunctly, from parts of the Sudan Savanna, Guinea Savanna, Rainforest, Afromontane–Afroalpine, Somalia–Masai Bushland, Coastal Forest Mosaic and Zambezian Woodland BZs, and from the Rainforest–Savanna Mosaics. Recorded from Senegal to Cameroon and SW Chad, from Congo, Angola and DR Congo, and from Sudan, Ethiopia and Somalia southwards to NE Botswana, the middle Zambezi valley in Zimbabwe, and Malawi. Also Zanzibar I. Map based on Van Cakenberghe & De Vree (1985) with some additional records (e.g. Cotterill 1996a). Gaps in the distribution, especially in Mozambique, probably reflect insufficient sampling.

Habitat In West Africa, mostly recorded from lowland rainforest and adjacent rainforest–savanna mosaic habitats, but also recorded in *Isoberlinia* woodland and undifferentiated woodland. In NE DR Congo, only recorded in savanna habitats and not in forests (Lang & Chapin [1917a] as *N. major*, but these specimens were re-identified as *N. macrotis* by Koopman [1965]). In Ethiopia, recorded from 515 to 2200 m (Largen *et al.* 1974). In Tanzania, recorded from a coastal forest (Cockle *et al.* 1998) as well as other habitats. In Malawi, recorded from miombo and mopane woodlands, riverine woodland and mosaics of thicket-clump, woodland and grassland savannas; 100–900 m (Happold *et al.* 1987). In southern Africa, mostly recorded below 1000 m, from riverine forests and riverine woodlands along permanent rivers and also seasonally dry waterways, in semi-arid savanna areas.

Abundance Uncertain. Comparatively uncommon in collections. Not common in West Africa according to Rosevear (1965), although ‘reasonably common’ in Senegal (T. S. Jones in Grubb *et al.* 1998).

Rarely encountered at the periphery of its geographic range in south-central Africa and southern Africa (Smithers 1983, Cotterill 1996a, P. D. F. Cotterill unpubl.). Widespread in Malawi, but uncommonly encountered (Happold & Happold 1997) except in Liwonde N. P. where 8 of 12 culverts investigated were occupied as day-roosts in April 1985 (Happold *et al.* 1987).

Adaptations Aspect ratio very low; wing-loading very low; wing-tip very rounded. Flight slow with great manoeuvrability. Can take off from the ground; probably able to hover briefly. Turns by banking (minimum radius <25 cm) and by stalling-and-twisting; individuals sustained flight within a 1×1×1 m enclosure for up to seven circuits/flight (4 bats, 10 flights each; M. Happold unpubl.). Day-roosts include hollow trees and logs, caves, abandoned mines and burrows, dry wells, dimly lit culverts under roads, dark cellars and human dwellings (Rosevear 1965, Poché 1975, Smithers 1983, Grubb *et al.* 1998). Hangs freely from ceilings. Sometimes roosts with *Hipposideros caffer* and *H. ruber*. At ambient temperatures of 20–24 °C, captive bats did not become torpid by day, and wild bats found in culverts during the cool-dry season in Malawi were active. Predicted mean maximum urine concentration is comparatively low (3257 mOsmol/kg), implying that *N. macrotis* is dependent on water for drinking (Happold & Happold 1988).

Foraging and Food Based on wing morphology, predicted to forage by hovering and gleaning, and its prey includes insects that are probably gleaned rather than taken in aerial pursuit (Whitaker & Black 1976, Findley & Black 1983). Stomach contents of five individuals from C Zambia contained predominantly large orthopterans (51% by volume), scarab beetles (27%) and termites (17%) (Whitaker & Black 1976).

Echolocation No information.

Social and Reproductive Behaviour Usually reported roosting singly or in small groups, but a colony of ca. 100 was found in a hollow baobab *Adansonia* in Senegal (Verschuren 1982). In 12 culverts in Liwonde N. P. (Malawi) in Apr, adult ♂♂ (with abdominal testes) were found roosting singly (n = 3); one group comprised one adult ♂ with scrotal testes, one ♀ with neonate, one adult ♀ (not palpably pregnant nor lactating) and three subadult ♀♀; a second group included one adult ♂ (testes scrotal), four adult ♀♀ (not palpably pregnant nor lactating) and two escapees; and a third group included an adult ♂ (testes scrotal) and one escapee. Nine years later, the same culverts contained only adult ♂♂ roosting singly (two with abdominal testes in Jan; one with abdominal testes and one with scrotal testes in Dec) (M. Happold unpubl.). The mating system cannot be determined from this limited data. Adults hang without touching neighbouring adults. In captivity, when a mother is resting, her baby hangs head-downwards with its feet hooked into the mother’s interfemoral membrane. If disturbed, the position of the young is rapidly adjusted before the mother flies away with the baby very firmly attached: the baby faces the mother’s head and holds on with its mouth attached to a nipple or pelage, its thumbs gripping the mother’s pelage or wing-membrane, and its toes gripping her pelage or interfemoral membrane. The thumbs and feet are very well developed, even in neonates.

Reproduction and Population Structure Litter-size: one. Reproductive chronology not known in detail. At 03° 22' S (Mto-wambo, Tanzania) in Dec, 2 of 13 adult ♀♀ were pregnant for the first time, two were lactating and also in oestrus, and nine were lactating and also pregnant (with foetuses up to 12 mm in length), indicating postpartum oestrus (Matthews 1939, 1941). The ovaries of these bats contained ripening follicles indicating the likelihood of a third oestrus cycle during the forthcoming lactation period, but the total number of litters/♀/year is not yet known. At ca. 15° S (Liwonde N. P., Malawi), 1 of 2 ♀♀ was post-lactating in Feb (the other subadult or inactive); 1 of 6 ♀♀ lactating and five post-lactating (also one neonate and one non-volant juvenile) in Apr; 1 of 1 lactating in Jun; no useful data for other months. These data are inconclusive, but indicate some births in wet season (ca. Dec) and early dry season (ca. Apr, May) and lack of close synchrony in ♀♀ (including those in same colony); no evidence to prove or disprove polyoestry in this population (Happold & Happold 1990a, M. Happold unpubl.).

Predators, Parasites and Diseases Ectoparasites include a bug *Eothenes nycteridis* (Hemiptera: Polyctenidae); bat-flies *Penicillidia pachymela*, *P. allisoni* (Diptera: Nycteribiidae), *Raymondia alulata*, *R. scopigera* (Diptera: Streblidae); and mites *Ancystropus zeleborii*, *Paraperiglischrus rhinolophinus*, *P. moucheti* (Acari: Spinturnicidae), *Bewsiella aelleni*, *Steatonyssus afer* (Acari: Macronyssidae), *Microtrombicula nycteris* (Acari: Trombiculidae), *Whartonia atracheata* (Acari: Leeuwenhoeekiidae), *Psorergatoides nycteris* (Acari: Psorergatidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Probably threatened by destruction of habitat by elephants and humans, in parts of its savanna range.

Nycteris major DJA SLIT-FACED BAT (JA SLIT-FACED BAT)

Fr. Nyctère du Dja; Ger. Dja Schlitznasen-Fledermaus

Nycteris major (K. Andersen, 1912). Ann. Mag. Nat. Hist., ser. 8, 10: 547. Dja River, Cameroon.

Taxonomy Originally *Petalia major*. Species-group: *arge*. Synonyms: *avakubia*. Considered a subspecies of *N. arge* by some authors, but Van Cakenberghe & De Vree (1985) and unpublished data (J. Fahr) show that it is a distinct species found in sympatry with *N. arge* at several localities (see Distribution). Chromosome number: not known.

Description Small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-sized for a *Nycteris* (FA: 47.5 ± 1.0 [45–49] mm, GLS: 20.4–22.4); upper incisors apparently bicuspid; posterior lower premolar large; tragus with marked concavity in posterior margin; E: 27–31 mm, Tib: 24–28 mm, 53–59% of FA. Not easily distinguished from *N. arge*. Pelage, loose, fluffy. Dorsal pelage variable: medium brown, rusty-brown to dark brown. Ventral pelage similar but paler. Ears broad and rounded; long for a *Nycteris* but of medium relative length (62 [58–65]% of FA). Tragus with well-defined concavity ('kink') at centre of posterior margin. Muzzle of naked appearance and pink. Wing-membranes blackish-brown. Tibia long for a *Nycteris* and also relatively long (56 [53–59]% of FA). Bacular morphology not known.

Skull with sagittal crest moderately to well developed. Upper incisors apparently usually bicuspid, but one specimen from Cameroon had unicuspid inner upper incisors (Perret & Aellen

1956). Posterior lower premolar comparatively large (reaching well above cingula of adjacent teeth and equal or almost equal to height of anterior cusp of first molar) and within tooththrow.

Geographic Variation Uncertain. Specimens from central Africa might average somewhat larger.

Similar Species Three other African *Nycteris* have the following combination of characters: upper incisors bicuspid; posterior lower premolar large; tragus with posterior margin concave (Table 18, p. 441):

Nycteris nana. Much smaller (FA: 32–37 mm; GLS: 15.6–17.0 mm).

N. intermedia: Much smaller (FA: 36–38 mm; GLS: 17.5–18.7 mm).

N. arge. Almost always smaller (FA: 42.1 ± 1.0 [39–46] mm; GLS: 19.9 [19.2–20.4] mm). Concavity in posterior margin of tragus poorly defined. According to Eisentraut (1956) the claws of thumbs and feet are more pointed and slender in *N. arge* than in *N. major*, but this was questioned by Rosevear (1965) and Van Cakenberghe & De Vree (1985). In some specimens there is overlap in univariate measurements between *N. arge* and *N. major* and multivariate analysis is needed to distinguish between them (Van Cakenberghe & De Vree 1985).

Distribution Endemic to Africa. Apparently restricted to the Rainforest BZ (Western, West Central, East Central and South Central Regions). Known from only 12 localities in Guinea (Ziéla, Mt Nimba; MNHN), Liberia, Côte d'Ivoire, Cameroon, DR Congo and Zambia (Van Cakenberghe & De Vree 1985, J. Fahr unpubl.). A record from Bimbereke (Benin) by Robbins (1980) was based on a misidentified *N. macrotis* (J. Fahr unpubl.). Specimens from Boma and Macaco (DR Congo), originally published as *N. major* by Kershaw (1923) and Schouteden (1947), have been re-identified as *N. macrotis* by Hayman *et al.* (1966) and Van Cakenberghe & De Vree (1985). A record from Yankari G. R., Nigeria, based on teeth and bones from owl pellets (Demeter 1981) is excluded here as it is more likely to be that of *N. macrotis* – it seems difficult at best to distinguish *N. major* and *N. macrotis* with certainty from bones and teeth alone, and the habitat (Sudan Savanna BZ, 09° 45'N) is almost certainly unsuitable for *N. major*. *Nycteris major* has been found sympatrically with *N. arge* near Mt Nimba (Liberia, Guinea), in Taï N. P. (Côte d'Ivoire), near Dja R. (Cameroon) and Avakubi (DR Congo).

Habitat Mainly recorded in lowland rainforest and coastal forest, but also recorded from one locality in flooded grassland with areas of Itigi thicket and woodland (Mweru Wantipa, Zambia; Ansell 1978).

Abundance One of the rarest nycterids and by far the rarest species in the *N. arge* group.

Adaptations Has been found by day in large, hollow, standing trees with holes near the base. A single specimen was found in a house (Lang & Chapin 1917b, as *N. avakubia*). The roosts are commonly shared with *Hipposideros cyclops* and, in one case, also with the mouse *Praomys tullbergi* (Eisentraut 1956, Verschuren 1976, Fedden & Macleod 1986).

Foraging and Food Forages close to the ground in the understorey of the forest. In Taï N. P., Côte d'Ivoire, a single individual was captured at a height of 1.9 m. Presumably gleans its prey from the vegetation and probably also from the ground. Details of diet not known: presumably arthropods, and, based on this bat's size, might also include small vertebrates.

Social and Reproductive Behaviour Found singly or in small groups. One non-reproductive group consisted of one adult ♂ and two adult ♀♀ (Cameroon; Eisentraut 1956). In Liberia, Verschuren (1976) found a pair in one hollow tree and a single ♂ in another. One pregnant ♀ roosted singly (Fedden & Macleod 1986).

Reproduction and Population Structure Litter-size: one. Reproductive chronology: not known. At 04° 38'N in Cameroon, a pregnant ♀ was reported in Jan (Fedden & Macleod 1986), and at 07° 30'N (near Mt Nimba, Liberia), another (with a 4 g foetus) was reported in mid-Feb (Verschuren 1976). At 06° 54'N in Côte d'Ivoire, a ♀ with a juvenile was captured in early Mar (USNM). For all of these localities, there are no data for other months, and therefore the limited observations are inconclusive.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Data Deficient.

Its population trend, the extent of its occurrence in central Africa, and its natural history and major threats are not known, but this species is probably threatened by fragmentation and decline of suitable habitat. Known from only 12 localities and ca. 16 specimens. Apparently largely dependent on forest habitat and might be much more affected by degradation and logging than any other nycterid.

Nycteris nana DWARF SLIT-FACED BAT

Fr. Nyctère naine; Ger. Kleinste Schlitznasen-Fledermaus

Nycteris nana (K. Andersen, 1912). Ann. Mag. Nat. Hist., ser. 8, 10: 547. Benito River, Equatorial Guinea.

Taxonomy Originally *Petalia nana*. Species-group: *arge*. Synonyms: *tristis*. Subspecies: none. Chromosome number: not known.

Description Very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; marginally the smallest species of *Nycteris* (FA: 32–37 mm, GLS: 15.6–17.0 mm); upper incisors bicuspid; posterior lower premolar large; tragus with marked concavity in posterior margin; E: 19–23 mm; Tib: 14–17 mm, 40–47% of FA. Sexes similar. Pelage loose, fluffy; mid-dorsal hairs 7–11 mm. Dorsal pelage variable: medium to dark brown. Ventral pelage similar but paler. Verschuren (1957) reported an albino from Garamba N. P., DR Congo. Ears broad and rounded, short for a *Nycteris* and also relatively short (60 [53–66]% of FA); dark brown or blackish with basal third of inner side much paler. Tragus with a well-defined concavity ('kink') at centre of the posterior margin. Muzzle of naked appearance and pink. Noseleaf, tragus and chin usually whitish or cream. Wings and interfemoral membrane dark brown or blackish-brown. Tibia short for a *Nycteris* and also relatively short (44 [40–47]% of FA). Baculum tip simple (Figure 94b; Thomas *et al.* 1994).

Skull with sagittal crest absent or consisting merely of an anterior rudiment. Upper incisors bicuspid. Posterior lower premolar comparatively large (reaching well above cingula of adjacent teeth and equal or almost equal to height of anterior cusp of first molar) and in toothrow.

Geographic Variation None.

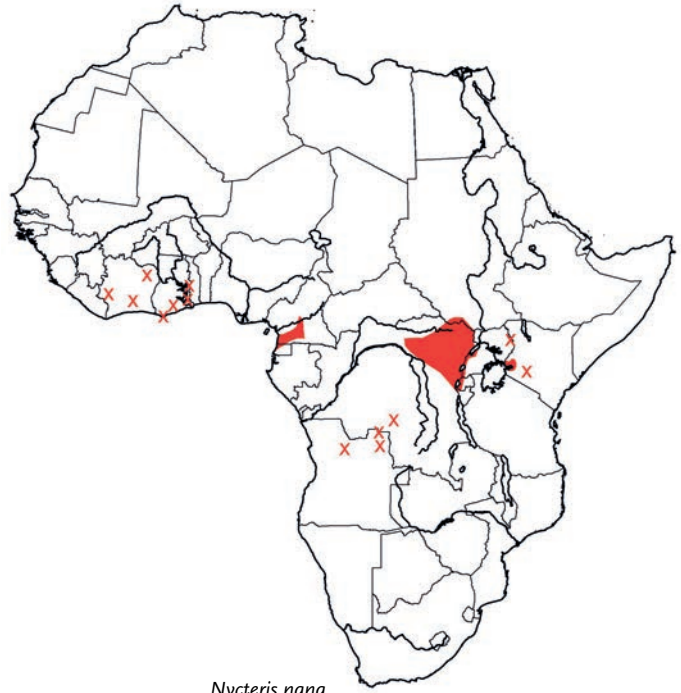

Similar Species Three other African *Nycteris* have the following combination of characters: upper incisors bicuspid; posterior lower premolar large; tragus with posterior margin concave (Table 18, p. 441):

Nycteris intermedia. Larger (FA: 36–38 mm; GLS: 17.5–18.7 mm). Tibia >50% of FA.

N. arge. Much larger (FA: 39–46 mm; GLS: 19.2–20.4 mm). Tibia >48% of FA. Ears comparatively longer (25–34 mm). Concavity in posterior margin of tragus poorly defined.

N. major. Much larger (FA: 45–49 mm; GLS: 20.4–22.4 mm).

Distribution Endemic to Africa. Apparently restricted to the Rainforest BZ (Western, West Central, East Central and South Central Regions), the Rainforest–Savanna Mosaics, and Afromontane–Afroalpine BZ within or near these zones. Known from Côte d'Ivoire, Ghana, Cameroon, Equatorial Guinea (excluding Bioko I.), Sudan, DR Congo, Uganda, Burundi (Bukinyanya, Kibira N. P., FMNH), Kenya and Angola. The distribution is patchy but this species is regularly recorded and therefore the gaps are not likely to only reflect insufficient sampling. Records from Gombe Stream N. P., Tanzania (Howell & Wrangham 1974) and Bengoué, Gabon (Brosset 1966) have been re-identified as *N. intermedia* (Van Cakenberghe & De Vree 1985).

*Nycteris nana*

Habitat In contrast to other members of the *arge* species-group, *N. nana* is often recorded from drier types of forest and seems to avoid the wettest parts of West Africa in Sierra Leone, Liberia, Côte d'Ivoire and Ghana. About half of the locality records are in rainforest–savanna mosaic, and most other localities are in lowland rainforest (both wetter and drier types), and montane forests flanking the Albertine Rift. Less often recorded in coastal forest, *Acacia–Commiphora* bushland and thicket, and *Isoberlinia* woodland.

Abundance Uncertain. Within the *arge* species-group, much rarer than *N. arge* but much more common than either *N. intermedia* or *N. major*.

Adaptations Occupies a wide variety of day-roosts and has been found in standing hollow trees, in caves, mines, culverts, in a hole of a Giant Pangolin, and under a bridge (in a narrow gap near the pier) (Verschuren 1957, Kingdon 1974, Heller *et al.* 1994, J. Fahr unpubl., MHNG, ROM). In NE DR Congo, found regularly in the upper parts of hollow trunks of *Canarium schweinfurthii*, *Halea stipulosa*, *Macaranga* sp., *Pseudospondia microcarpa*, *Randia* sp., *Spondianthus preussii* and *Syzygium guineense* (Verschuren 1957). Rosevear (1965) noticed that most of these trees are typical of younger secondary regrowth rather than mature forest. However, Rosevear (1965) concluded that the actual species of tree is unlikely to be of importance, provided a suitable cavity is present. When disturbed at their roosts during the day, individuals readily take flight (Verschuren 1957, Kingdon 1974, J. Fahr unpubl.). One ♀ roosted in a hollow tree (*Randia* sp.) that was also occupied by a Barn Owl *Tyto alba* (Verschuren 1957).

Foraging and Food Forages close to the ground in the understorey of the forest. In Comoé N. P. (Côte d'Ivoire), two individuals were captured 1.1 m above ground, in mist-nets set 0–25 m above ground (J. Fahr unpubl.). Gleans insects from vegetation and probably also from the ground. Diet not known but likely to consist of rather soft-bodied arthropods.

Social and Reproductive Behaviour Usually found in small groups or pairs, either with or without young (Verschuren 1957, Heller *et al.* 1994). Kingdon (1974) found a pair inhabiting a hole dug by a Giant Pangolin *Smutsia gigantea* over a period of eight years, although he could not determine if they were the same individuals.

Reproduction and Population Structure Litter-size: one (n = 4) (Verschuren 1957). According to Verschuren (1957), the reproductive chronology at 04° 10' N (Garamba N. P., NE DR Congo) is seasonal monoestry, but this needs confirmation. Verschuren (1957) reported pregnant ♀♀ in Jan–Apr (n = 4), lactating ♀♀ from Mar–May (n = 5) and a post-lactating ♀ with a juvenile in May (but he did not give data for other months and did not mention if ♀♀ in other reproductive states were captured during this period). The young are suckled for 45–60 days (Verschuren 1957). Data from other localities are inconclusive.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

Nycteris parisii PARISI'S SLIT-FACED BAT

Fr. Nyctère de Parisi; Ger. Parisis Schlitznasen-Fledermaus

Nycteris parisii (De Beaux, 1923, [publ. 1924]). Atti. Soc. Ital. Sci. Nat. 42: 254. Ballei Uen, lower Uebi Scebeli, Somalia (see Hill 1975: 507).

Taxonomy Originally *Petalia parisii*. Species-group: *macrotis*. Synonyms: *benuensis*. Subspecies: none. Based on similarities in craniodental measurements, considered a synonym of *N. woodi* by Van Cakenberghe & De Vree (1985), Koopman (1993) and Griffiths (1994), but considered to be a distinct species by Rosevear (1965), Hayman & Hill (1971), Thomas *et al.* (1994) and Simmons (2005). Although *N. parisii* is very similar to *N. woodi* in craniodental proportions (notably widths and lengths of maxillary and mandibular tooththrows; Van Cakenberghe & De Vree 1985), the baculum of *parisii* is most similar in morphology to that of *N. macrotis* (Thomas *et al.* 1994). Chromosome number: not known.

Description Very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; one of the five smallest and most gracile species of *Nycteris* (FA: 38–41 mm); upper incisors bicuspid; posterior lower premolar small; tragus semi-lunate with posterior margin usually smoothly convex; E: 20–23 mm, 54.4 (51–56)% of FA. Not easily distinguished from *N. woodi*. A very poorly known species. Sexual dimorphism: no information. Pelage soft, loose and fluffy; mid-dorsal hairs ca. 10 mm. Dorsal pelage brownish-grey; hairs slightly paler at base. Ventral pelage dark grey. Ears short for a *Nycteris* (20–23 mm), and relatively short (54.4 [51–56]% of FA, n = 3) (cf. *N. woodi*). Tragus semi-lunate; posterior margin smoothly convex (similar to *N. macrotis*, Figure 93f); lobe at base of posterior margin comparatively large and laterally orientated (cf. *N. woodi*). Eyes

small. Wings and interfemoral membrane brown. Tibia of medium length for a *Nycteris* and also of medium relative length (52 [48–56]% of FA, n = 3). Baculum comparatively large (4.30 mm, n = 1); shaft long, parallel-sided, essentially straight, thickening towards base; base expanded, in lateral profile angled ventrally; tip expanded, trifid with three variably developed processes (Thomas *et al.* 1994).

Upper incisors bicuspid. Lower posterior premolar very small (not rising above cingula of adjacent teeth) and in tooththrow.

Geographic Variation None recorded.

Similar Species Only two other African *Nycteris* have the following combination of characters: upper incisors bicuspid; lower posterior premolar small; tragus with posterior margin convex (Table 18, p. 441):

Nycteris macrotis. Usually larger (FA: 48.1 [40–55] mm). Ventral pelage not dark grey (most often pale grey).

N. woodi. Ears comparatively longer (28–35 mm) and relatively longer (79.5 [73–89]% of FA). Baculum shorter (2.5–2.7 mm), with tip unexpanded and simple. Ventral pelage paler to much paler than dorsal pelage (sometimes almost white).

Distribution Endemic to Africa. Only known from the Sudan Savanna BZ in N Cameroon, and from the Somalia–Masai Bushland

Nycteris parisii

BZ and Coastal Forest Mosaic BZ in Ethiopia and Somalia. Recorded from Lower Shabeelle and the Jubba Valley in Somalia (De Beaux 1923b, Varty & Hill 1988), NE of L. Stephanie, Gemu Gofa in Ethiopia at 500 m (Hill 1975), and Rei Bouba on a tributary of the Benue R. in N Cameroon (Aellen 1952, as *N. benuensis*). A specimen from S Tanzania (BMNH 64.1473), provisionally identified as *N. p. benuensis* by Hayman & Hill (1971), is considered here to represent *N. woodi*.

Habitat The type locality is believed to be near a well or waterhole where there was a temporary marsh in the wet season (Zammarano 1930, in Hill 1975). The specimen from Jubba Valley was taken in riverine forest on bank of Jubba R. At this locality, many of the trees and shrubs are evergreen, individual trees reach 30 m but the

overstorey is typically only 10–15 m high, and the rainfall is bimodal (Apr–Jun and Oct–Dec) (Varty & Hill 1988). The N Cameroon specimens were collected from an area of degraded savanna and woodland near the river, where swamps or marshes were important (Aellen 1952).

Abundance Uncertain. Presumably rare as apparently only five specimens have been collected.

Remarks One of the most poorly known African bats. Nothing else is known of its biology.

Conservation IUCN Category: Data Deficient.

F. P. D. Cotterill

Nycteris thebaica EGYPTIAN SLIT-FACED BAT

Fr. Nyctère de la Thébaïde; Ger. Ägyptische Schlitznasen-Fledermaus

Nycteris thebaica E. Geoffroy, 1818 (1813 in some publications). Descrip. de l’Egypte 2: 119. Thebes (near Luxor), Egypt.

Taxonomy Species-group: *thebaica*. Synonyms in Africa: *adana*, *affinis*, *albiventer*, *angolensis*, *aurantiaca*, *brockmani*, *capensis*, *damarensis*, *discolor*, *fuliginosa*, *geoffroyi*, *labiata*, *media*, *revoilii*, *senegalensis*. Also *aethiopicus* (*nomen nudum*). Subspecies: seven; six in Africa. Chromosome number (Zimbabwe, Namibia, South Africa): 2n = 42; aFN = 78 (Peterson & Nagorsen 1975, Rautenbach *et al.* 1993).

Description Small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-small for a *Nycteris*; upper incisors bicuspid; posterior lower premolar very small; tragus pear-shaped with posterior margin deeply notched; E: 28–39 mm. Not easily distinguished from *N. gambiensis* but, in West Africa where the two species are sympatric, *N. thebaica* is on average

the larger species (FA: 44.0 ± 1.31 mm; Tib: 22.24 ± 1.06 ; GLS: 18.68 ± 0.43 ; Van Cakenberghe & De Vree 1998). Sexes similar in colour; ♀♀ slightly larger on average than ♂♂ in some series. Pelage soft, fluffy; mid-dorsal hairs ca. 10 mm. Dorsal pelage pale grey, beige, reddish-brown to dark brown; individuals from drier areas paler; hairs unicoloured or grey at base. Ventral pelage paler to much paler than dorsal, often greyish-white, sometimes almost white. Some individuals have a reddish ruff. In orange-phase, dorsal pelage bright orange. Ears long for a *Nycteris*, but of medium relative length (70 [56–88]% of FA). Tragus inverted pear-shaped with deep notch in posterior margin, tip hairy (Figure 93h). Eyes minute. Wings and interfemoral membrane dark grey or greyish-brown. Tibia of medium length for a *Nycteris* (24.0 [21–26] mm), and of

medium relative length (49 [38–61]% of FA). Baculum tip simple (Thomas *et al.* 1994).

Skull with sagittal crest low. Upper incisors bicuspid. Anterior lower premolar minute (not rising above cingula of adjacent teeth), sometimes within toothrow, sometimes displaced lingually to a greater or lesser extent, but anterior lower premolar and first molar usually separated by pronounced gap.

Geographical Variation Gray *et al.* (1999) list and map six African subspecies, but comment that the subspecific classification is uncertain:

N. t. brockmani: S Somalia, Djibouti, NE Ethiopia.

N. t. thebaica: Egypt and N Sudan to Senegal, and also Morocco.

N. t. labiata: N Ethiopia and C Sudan to N Tanzania and Uganda.

N. t. capensis: S Tanzania, SE DR Congo and Zambia to Cape of Good Hope.

N. t. angolensis: Coastal SW Angola.

N. t. damarensis: SC Angola, Namibia and Botswana.

The subspecies differ in body and skull measurements; colour variation does not follow a geographic pattern (Van Cakenberghe & De Vree 1998) although individuals from drier habitats are sometimes paler.

Similar Species Only one other African *Nycteris* has the following combination of characters: upper incisors bicuspid; posterior lower premolar small; tragus (without doubt) pear-shaped with posterior margin deeply notched (Table 18, p. 441):

Nycteris gambiensis: ventral pelage only slightly paler than dorsal pelage; on average smaller (FA: 40.1 ± 1.4 mm; Tib: 19.9 ± 0.99 mm; GLS: 17.58 ± 0.36 mm); for comparison, see Similar Species of *N. gambiensis* for measurements of West African *N. thebaica*. Anterior lower premolar and anterior molar in contact or almost so. West Africa and Cameroon only.

Nycteris vinsoni, if proved to have a pear-shaped tragus with a notch in the outer margin, is probably a valid species (see profile), which also resembles *N. thebaica* but is probably, on average, larger (FA: 51 mm). Mozambique.

Distribution In Africa, known from the Mediterranean Coastal BZ in Morocco (eight localities), and from the Nile Valley in the Sahara Arid BZ. South of the Sahara, very widespread and recorded from all biotic zones although only very marginally in the Rainforest BZ and apparently absent throughout much of the Somalia–Masai Bushland BZ. The apparent gap between Morocco and Senegal possibly reflects insufficient sampling (Van Cakenberghe & De Vree 1998). Occurs on Mafia I. (Kock & Stanley 2009) as well as on Pemba I. and Zanzibar I. Extraliminally: Israel, Sinai, central Arabia. Has the largest distribution of any nycterid. Map based on Van Cakenberghe & De Vree (1998). Maps drawn by Kingdon (1974), Smithers (1983) and Gray *et al.* (1999) indicate occurrence in several regions for which there are apparently no records (e.g. Algeria, Tunisia, Libya, most of C and S Somalia, large parts of the South-West Arid BZ and much of the Highveld Grassland BZ).

Nycteris thebaica

Habitat In NE Africa, found in riverine habitats near Nile R. In West, north-central and eastern Africa, mostly open woodland savannas, and riverine or oasis habitats in more arid regions; also montane habitats in Ethiopian Highlands and occasionally clearings in lowland rainforest. In Zambia and Malawi, widespread in woodland savannas but not yet recorded from montane habitats (Ansell 1978, Happold *et al.* 1987). In southern Africa, mainly found in woodland savannas but also found in dense coastal and riverine forests; possibly limited to riverine habitats in arid regions; not known from colder Highland, Montane and Mistbelt bioregions (Smithers 1983, Taylor 2000, R. T. F. Bernard unpubl.).

Adaptations Aspect ratio very low; wing-loading very low; wing-tip very rounded (Figure 92). Flies slowly with great manoeuvrability. Can take off from ground and hover briefly; turns by banking (minimum radius <25 cm) and by stalling-and-twisting. Individuals sustained flight within a 1×1×1 m enclosure for up to seven circuits/flight (5 bats, 10 flights each; M. Happold unpubl.). By day, hangs freely from ceilings of caves and cave-like places (including mines, tombs, military bunkers, thatched huts and other buildings), rock crevasses, hollow trees, cavities under roots, Aardvark burrows, holes in termitaria, road culverts, wells, pit-latrines and fireplaces. Great manoeuvrability allows it to fly to roost-sites inaccessible to bats belonging to other families, but it sometimes shares more accessible day-roosts with other bats, including species of *Rousettus*, *Taphozous*, *Rhinolophus*, *Asellia*, *Myotis* and *Miniopterus*. Some switching between different roosts was observed during an 8-day study by Aldridge *et al.* (1990); sometimes this is a response to the presence of predatory *Nycteris grandis*. Migration occurs in South Africa, possibly in response to fluctuations in availability of food and the need for more food while reproducing (Bernard 1980a). In KwaZulu–Natal (South Africa), coastal roosts are occupied year-round but inland roosts are occupied only in winter (Bernard 1982a). Does not become

torpid during day under natural temperature regimes (Happold & Happold 1988), and does not hibernate (Bernard 1982a). Predicted mean maximum urine concentration is comparatively low (2886 mOsmol/kg), implying dependence on water for drinking (Happold & Happold 1988). In captivity, feeds well but often refuses to drink and dies after 4–5 days. For information published since this profile was submitted, see Monadjem (2006a, 2006b) and Monadjem *et al.* (2009, 2010).

Abundance Uncertain, but common in collections and thought to be common (at least locally) throughout much of geographic range.

Foraging and Food Forages for volant and non-volant arthropods by slow-hawking, fly-catching, foliage-gleaning and ground-gleaning, in places of moderate to dense clutter including in, under and just above tree canopies, in undergrowth, over streams, near lights and buildings (e.g. Fenton *et al.* 1983, Lindeque 1987, Aldridge *et al.* 1990, Seamark & Bogdanowicz 2002). Often forages very near ground; based on wing morphology, probably forages within short distance of day-roost. While fly-catching or ground-gleaning from a perch, hangs by one foot, rotates the body and turns the head while listening for prey-generated sounds. In response to sounds, directs the head towards the source, moves the ears rapidly to and fro, and then attacks – possibly using vision (in spite of its minute eyes) as well as echolocation to locate the prey's exact position. Volant prey taken in flight. Non-volant prey taken by hovering and gleaning from leaves, branches, walls, rockfaces and other surfaces. Alternatively, lands on ground, envelops the prey with the wings and uses the interfemoral membrane to transfer it to the mouth. Small insects (<14 mm) are consumed immediately; larger prey is taken back to the perch. Wings and legs of prey are usually discarded and accumulate under regularly used perches. Feeds opportunistically on wide variety of insects including Orthoptera, Coleoptera, Hemiptera and Lepidoptera (primary prey), and Homoptera, Isoptera, Neuroptera, Hymenoptera and Diptera, and possibly prefers hard-shelled prey (e.g. Fenton & Thomas 1980, LaVal & LaVal 1980, Seamark & Bogdanowicz 2002). Wings of the African bollworm *Helicoverpa armigera*, which is an agricultural pest, have been found under a feeding-perch on the coast of the Eastern Cape Province of South Africa (R. T. F. Bernard pers. obs.). Also eats scorpions (Scorpiones) and sun-spiders (Solifugae) (Felten 1956). Geckos, a frog and a small fish were reported in the diet by Seamark & Bogdanowicz (2002), but vertebrates are probably eaten only rarely (cf. *N. grandis*). Diet is influenced by seasonal changes in both absolute and relative abundance of different insects, geographical area and the condition of the bat (reviewed by Seamark & Bogdanowicz 2002). However, a year-round investigation in KwaZulu–Natal showed that prey varied significantly by order but not by season, although a significant interaction between prey-category and season suggested that these two factors are not independent from each other (Seamark & Bogdanowicz 2002). These authors conclude that dietary flexibility combined with versatile foraging behaviour has allowed this species to inhabit a variety of habitats over a wide geographic range.

Echolocation Echolocation calls (phase unspecified) are very low intensity, short duration (<2 ms), multi-harmonic, broad bandwidth,

steep FM sweeps. Data and sonogram in Taylor (2000) indicate that the fundamental frequency falls from ca. 27 to 20 kHz and that much energy is also placed in the second and third harmonics. The calls can only be picked up within 50 cm of bat-detectors.

Social and Reproductive Behaviour Usually roosts in groups of three to several hundred; occasionally roosts singly or in pairs. Adults hang apart in loose aggregations. In Swaziland, where roosts are occupied throughout the year, the ratio of ♂♂ to ♀♀ is 1 : 0.4 (A. Monadjem pers. comm.). Thirteen of 15 culverts under a 3 km long road were occupied by six groups of ♀♀; ♀♀ tended to show fidelity to one culvert but occasionally roosted in adjacent culverts. Males also roosted in these culverts, but probably moved between non-adjacent culverts more often than the ♀♀ (A. Monadjem pers. comm.). Bats at day-roosts, and also when hanging within 2 m of each other at night-roosts, emit a comparatively long and high intensity, tonal, narrow-bandwidth vocalization (audible to humans), which sometimes attracts other conspecifics (Aldridge *et al.* 1990). A comparatively long and high intensity, broad bandwidth call (also audible to humans) is emitted by bats leaving the roost. Courtship behaviour includes 'frenzied' flying, head-butting in flight and neck-biting; copulation occurs while the bats hover, and is repeated several times (Lindeque 1987). At dusk, mothers carry their young, attached to a nipple, away from the day-roost, possibly to avoid predation by *N. grandis* (Aldridge *et al.* 1990).

Reproduction and Population Structure Litter-size: one. At ca. 29°S (KwaZulu–Natal, South Africa), the reproductive chronology is restricted seasonal monoestry, with copulation and fertilization in Jun; gestation (without any delays) lasting five months; parturition in early Nov; lactation lasting ca. two months; and a period of anoestrus between termination of lactation and onset of pro-oestrus in Apr (Bernard 1982a). Ovarian and vaginal activity peaks in Apr–early Jun, and again in Jul–Aug, the second peak possibly being a relict from polyoestrous ancestors. At 02°18'S (Masalani, near Kibwezi, inland Kenya; O'Shea & Vaughan 1980), at 7°S in coastal Tanzania (Howell 1976) and at 15–16°S in Malawi (Happold & Happold 1990a), the reproductive chronology is also restricted seasonal monoestry with births in Nov, Nov, and Oct–Nov, respectively. Based on limited data combined from widespread and diverse localities, Anciaux de Faveaux (1978) invalidly suggests that *N. thebaica* exemplifies 'continuous polyoestry' and has a gestation of three months, and this has been widely quoted, especially in the context of reproduction of *N. thebaica* in the tropics. However, for specific localities, his published data are either inconclusive or indicative of monoestry, contain no evidence of polyoestry, and do not indicate length of gestation. Clearly, the reproductive chronology in wet tropical habitats needs investigation.

The ratio of ♂♂ to ♀♀ at birth is 1 : 1. Based on recaptures of bats roosting in 13 culverts along 3 km of one road in Swaziland, survival during first year appears low, but increases thereafter; ca. 15% of ♀♀ and 10% of ♂♂ banded as juveniles were alive three years later (Monadjem 2006a). Of 39 ♀♀ banded as adults, 23% were alive in the same culverts 4.5 years later, whereas only one of 28 ♂♂ was re-captured after four years. Female values probably reflect true survival; dispersal might account for the apparent loss of ♂♂.

Predators, Parasites and Diseases Predators include owls *Bubo africanus* and *Tyto alba* (Demeter 1982, Perrin 1982), and probably the bat *N. grandis* (see species profile). Ectoparasites include a bug *Eothenes nycteridis* (Hemiptera: Polyctenidae); four species of fleas (Siphonaptera: Pulicidae, Ischnopsyllidae); 12 species of batflies (Diptera: Nycteribiidae, Streblidae); five species of ticks (Acari: Argasidae); and 11 species of mites (Acari) (Anciaux de Faveaux 1984). Duvenhage virus has been isolated from *N. thebaica* (Calisher *et al.* 2006).

Conservation IUCN Category: Least Concern.

Nycteris vinsoni VINSON'S SLIT-FACED BAT

Fr. Nyctère de Vinson; Ger. Vinsons Schlitznasen-Fledermaus

Nycteris vinsoni Dalquest, 1965. J. Mammal. 46: 256. Zinave, Mozambique.

Taxonomy Species-group: *thebaica* (if *vinsoni* is a valid species). Synonyms: none. Considered to be a synonym of *Nycteris macrotis luteola* by Kock (1969a), but this was rejected by Koopman (1975), who placed it as a species in the *thebaica* group based on his opinion, at that time, that the tragus was pear-shaped. Koopman (1994) was still of this opinion but, subsequently, he considered it a subspecies of *Nycteris thebaica* (Koopman 1993). Koopman's 1994 publication was actually written earlier than his 1993 publication. Based on data from the literature, Van Cakenberghe & De Vree (1998) treat *N. vinsoni* as a distinct species in the *N. thebaica* group. Here, the status of *vinsoni* is considered to be uncertain because the shape of the tragus is uncertain and this is a crucial character. The ears and tragi of both the holotype and the single paratype were singed and shrivelled by smoke and heat at the time of capture, and their shape has been distorted. The tragi were described as semi-lunate by Kock (1969a) and Koopman (1992), but pyriform (pear-shaped) by Koopman (1975, 1994). If the tragus is semi-lunate (i.e. *N. macrotis*-like), *vinsoni* is probably a synonym of *N. macrotis* because its measurements and tooth characteristics are similar to those of *N. macrotis*. On the other hand, if the tragus is pyriform (i.e. *N. thebaica*-like), *vinsoni* is probably a valid species because its skull dimensions exceed the maxima for *N. thebaica*. Chromosome number: not known.

Description A small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; medium-sized for a *Nycteris* (FA: ca. 51 mm); upper incisors bicuspid; posterior lower premolar small; tragus of uncertain shape; E: uncertain; Tib: 25 mm. Known only from two specimens. Described as similar in general proportions to *N. thebaica*, but larger and stouter. Two colour-phases, grey and orange. Ears apparently short for a *Nycteris* (ca. 22 mm, cf. 26–40 mm in *N. thebaica* and 26–35 mm in *N. macrotis*). However,

because the ears and tragi were shrivelled by smoke and heat, the ear measurements are unlikely to be accurate. Tragus shape uncertain: has been described as both pyriform and as semi-lunate (see Taxonomy); according to Koopman (1994) it apparently lacks a notch or concavity in the outer margin. The FA of the holotype is given as 50.6 mm, which lies only just outside the standard deviation for *N. macrotis* and well within its range. In contrast, it is at the upper limit of the range for *N. thebaica*. The tibia is of medium length for a *Nycteris* (25 mm) and of medium relative length (49% of FA). Bacular morphology not known.

All skull dimensions lie comfortably within range for *N. macrotis*, but some dimensions are larger than the maxima for *N. thebaica*. The posterior lower premolar is minute and displaced lingually, which suggests affinity with the *macrotis* group but, in *N. thebaica*, the position of this premolar in the tooththrow is very variable (Van Cakenberghe & De Vree 1998).

Geographic Variation No information.

Similar Species

Nycteris thebaica and *N. macrotis*: see Description.

Distribution Endemic to Africa. Known only from the type locality, Zinave on the Save R. in Mozambique, in the Zambezi Woodland BZ.

Habitat The Save R. runs through mopane woodland in this area.

Remarks Nothing else is known about the biology of this species except that the two specimens, an adult ♂ and ♀, were roosting together in a hollow, 15 cm diameter, near the base of a large baobab tree *Adansonia* (Dalquest 1965).

Nycteris vinsoni

Conservation IUCN Category: Data Deficient.

Because the status of this taxon is uncertain, its conservation status cannot be evaluated realistically.

Nycteris woodi WOOD'S SLIT-FACED BAT

Fr. Nyctère de Wood; Ger. Woods Schlitznasen-Fledermaus

Nycteris woodi K. Andersen, 1914. Ann. Mag. Nat. Hist., ser. 8, 13: 563. Chilanga, Zambia.

Taxonomy Species-group: *macrotis*. Synonyms: *sabiensis*. Following Hayman & Hill (1971) and Thomas *et al.* (1994), not considered to include *N. parisii* although this form is considered to be a subspecies of *N. woodi* by Van Cakenberghe & De Vree (1985) and Koopman (1993). Subspecies: none. Chromosome number (South Africa): 2n = 42; aFN = 78. Nineteen pairs of biarmed autosomes and one pair of small acrocentric autosomes. X = medium-sized metacentric, Y = small acrocentric (Rautenbach *et al.* 1993).

Description Very small microbat with noseleaf comprised of a longitudinal slit bordered by fleshy outgrowths; one of the five smallest and most gracile species of *Nycteris* (FA: 35–42 mm); upper incisors bicuspid; posterior lower premolar small; tragus semi-lunate with posterior margin smoothly convex; E: 20–23 mm; 80 (74–89)% of FA. Not easily distinguished from *N. parisii*. Sexes similar. Pelage loose, fluffy; mid-dorsal hairs ca. 10 mm. Dorsal pelage pale silvery-grey, grey, rusty-brown or brown, sometimes with paler pelage on back of head and shoulders and sometimes with darker patches on sides of muzzle and at bases of ears; hairs (in paler specimens) paler with terminal quarter same as dorsal colour; in brown specimens, hairs are brown with dark brown at base. Ventral pelage paler to much paler, sometimes almost off-white. Ears grey, long for a *Nycteris* (31.7 [28–35] mm) and relatively long (80 [74–89]% of FA, n = 16) (cf. *N.*

parisii). Tragus very narrowly semi-lunate; posterior margin smoothly convex, upper margin flattened (cf. rounded in *N. hispida*); lobe at base of posterior margin comparatively small (cf. *N. parisii*). Eyes minute. Wing-membranes of grey-furred individuals are translucent grey. Those of brown-furred individuals are correspondingly light reddish-brown (Ansell 1967). Tibia short for a *Nycteris* (19.5 [16–22] mm), but of medium relative length (50 [41–54]% of FA). Baculum comparatively short (2.49–2.73 mm); shaft straight, parallel-sided; base expanded, in lateral view angled ventrally; tip simple, unexpanded (Thomas *et al.* 1994).

Skull with sagittal crest low. Upper incisors bicuspid. Posterior lower premolar small (not rising above cingula of adjacent teeth), within tooththrow or slightly to fully displaced lingually.

Geographic Variation None recorded.

Similar Species Only two other African *Nycteris* have the following combination of characters: upper incisors bicuspid; lower posterior premolar small; tragus with posterior margin convex (Table 18, p. 441):

N. macrotis. Usually larger and more robustly built (FA: 48.2 ± 2.0 [40–55] mm). Ears usually relatively shorter (65 [55–80]% of FA). Baculum with tip expanded and trifid.

*Nycteris woodi*

N. parisi. Ears comparatively shorter (20–23 mm) and relatively shorter (51–56% of FA, $n = 3$). Baculum longer (>4 mm), with tip expanded and trifid. Ventral pelage dark grey in the very few known specimens. Cameroon, Ethiopia, Somalia.

Distribution Endemic to Africa. Zambezian Woodland BZ. Recorded from C and E Zambia, S and N Zimbabwe at lower altitudes (<1100 m), S and C Malawi, and marginally in northern South Africa in the Limpopo valley (Ansell 1967, 1978; Van Cakenberghe & De Vree 1985; Cotterill 1996a). In Mozambique, one specimen is known from Chicoa (USNM), but *N. woodi* is probably more widespread along the Limpopo, Save and Zambezi valleys. A specimen (BMNH 64.1473) collected by C. J. P. Ionides from S Tanzania (? Liwale, not mapped) was identified provisionally as *N. parisi* by Hayman & Hill (1971), but subsequently considered to represent *N. woodi* by K. Koopman and J. E. Hill (Hill 1975). Smithers (1983) mentions a series collected from Rwanda (without further information), but this record is not mentioned by Van Cakenberghe & De Vree (1985).

Habitat Woodland savannas (including miombo and mopane woodlands) where suitable day-roosts are available.

Abundance Uncertain. Locally common in Zimbabwe, especially in the low-lying valleys of the Limpopo, Save and Zambezi rivers and their tributaries, including the Sebungwe Basin of N Zimbabwe (Cotterill 1996a). Rarely recorded in Malawi (Happold & Happold 1997), where known from only two localities: Chiromo (three specimens; R. C. Wood in Kershaw 1922, as *N. hispida*) and Kota Kota (= Nkotakota, one specimen; Van Cakenberghe & De Vree 1985). Known from only three localities in Zambia (Ansell 1978). Considered one of the rarest African nycterids by Van Cakenberghe & De Vree (1985).

Adaptations Aspect ratio very low; wing-loading very low (F.

P. D. Cotterill unpubl.). Flight slow and highly manoeuvrable; adept at flying through very cluttered habitats. Day-roosts include large hollows in trees (including *Kigelia africana* and *Adansonia digitata*), caves, rock-fissures, disused mine-workings, human dwellings and a culvert under a railway. Individuals hang freely. Uses night-roosts (including in open corridors in buildings in Sengwa Wildlife Research Area, Zimbabwe) underneath which discarded remains of prey have been found.

Foraging and Food Based on wing morphology, diet and captures in mist-nets and harp-traps, this species forages in highly cluttered habitats by gleaning; perhaps also uses other foraging strategies but this needs confirmation. Stomach contents of five individuals from C Zambia in wet season contained predominantly adult Lepidoptera (46% by volume), adult Coleoptera (scarab beetles) (20%), Lepidoptera larvae (17%) and unidentified larvae (1%), Isoptera (termites – 10%), Orthoptera (3%) and flies and spiders (3%) (Whitaker & Black 1976). Discarded remains of prey found beneath day-roost sites and feeding-perches in the Sengwa Wildlife Research Area (SWRA; Zimbabwe) included predominantly Lepidoptera and Orthoptera; in early Jan 1989, the most abundant remains were those of tettigoniids (bush katydids) *Plangia graminea* and *Melidia brunneri*. Lepidopteran prey were predominantly moths, but some butterflies (including *Charaxes brutus natalensis*, a large nymphalid) were also eaten (F. P. D. Cotterill unpubl.).

Echolocation Call-shape multiharmonic, steep FM. Lowest frequency 35 kHz; highest frequency 55 kHz; peak-frequency 43 kHz; intensity low (Fenton & Bell 1981, Fenton 1985); but, based on frequency-time structure as illustrated by Fenton & Bell (1981), the minimum and maximum frequencies are those of different harmonics and the bandwidth of each harmonic appears to be ca. 10 kHz.

Social and Reproductive Behaviour Roosts in small or large groups (colonies) (Cotterill 1996a). One group, comprised of one adult ♂ and four ♀♀, was found in a mine-adit in Zimbabwe. A colony of more than 40 individuals roosted in a store-room at SWRA. Four other colonies, each containing ca. 50 individuals, have been found in Zimbabwe (F. P. D. Cotterill unpubl.).

Reproduction and Population Structure Litter-size: one ($n = 3$). Reproductive chronology uncertain. In Zimbabwe, three ♀♀ were in early pregnancy in mid-Aug; ♀♀ with single neonates were observed in mid-Nov; volant young in mid-Dec; post-lactating ♀♀ and volant young in early Jan; and ♀♀ found during cool-dry season were neither visibly pregnant nor lactating (F. P. D. Cotterill unpubl.). These data are consistent with restricted seasonal monoestry, but this needs confirmation.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

However, threatened by loss of habitat in S Malawi (Happold & Happold 1997) and parts of Zimbabwe (F. P. D. Cotterill unpubl.). Pesticides and destruction of hollow baobabs used as roosts are likely to cause population numbers to decline.

| <i>Sauromys</i> (1 species) | Flat-headed Bat | p. 485 |
| <i>Tadarida</i> (28 species) | Tadarine Free-tailed Bats | p. 487 |

This is a polytypic family that is distributed throughout most of the tropical, sub-tropical and warm temperate regions of the world, in habitats ranging from rainforests to woodland savannas, dry bushlands, semi-deserts and deserts. There are 16 extant genera (of which three are monotypic) and 100 extant species: eight genera and ca. 33 species are found in Africa according to Simmons (2005). However, the taxonomy of this family is controversial (see below) and, here, the African species are provisionally placed in only six genera. Molossids have a mastiff-like face (Figure 32h), often with very wrinkled lips, sometimes with complexly folded ears, no noseleaf, and a long tail that projects through the posterior margin of the interfemoral membrane when these bats are not flying (Figure 33h). Most molossids fly very fast and high and are the nocturnal counterparts of swifts. Some of the African molossids are considered to be pests because they roost in large numbers in roofs and are very noisy and smelly. On the other hand, some of these bats feed mainly on moths and probably play a very important role in controlling moths that damage cotton and other crops.

African molossids are very small to medium-sized microbats with short, velvety pelage, which is sometimes greasy. Most species are dark brown or reddish-brown with a paler belly. Often they have a strong musky odour from secretions from glands in the skin. Many have a broad band of near-naked, wrinkled skin across their shoulders. The body is elongated and robust. The head is broad, flattish to very flat, and usually heavily jowled; the upper lips are often expansible and wrinkled into vertical folds; the lips and snout have long sensory hairs and short spoon-shaped bristles; the snout usually projects beyond the lower lip. When the mouth is wide open, the lips probably spread outwards to increase the gape and facilitate capture of prey (Vaughan 1966). The ears are forward-pointing; usually broad relative to their length; usually very large but often with creases enabling them to fold up in a somewhat fan-like manner. The margins are usually thickened with connective tissue and these strongly brace the ears during flight. The inner margins of the ears are thick and may be separated or joined in various ways, which are of diagnostic value (see below). In some species, this band, or the skin just behind or below it, carries a tuft of hairs that can be erected into an interaural crest (Figure 95f and g); in some species (but not all) the hairs of the crest appear to be scent-dispersing osmetrichia and probably arise from glandular tissue (Hickey & Fenton 1987). The tragus is small to minute. The eyes are moderately large for a microbat. The wings are typically very long and narrow; the thumb has a pad at its base; the second finger has a metacarpal and one vestigial phalanx (Figure 95a). The wing-membranes either have blackish-brown or white pigmentation, or are almost transparent. The hindlimbs are short and muscular, the soles are broad and

sometimes have a well-developed plantar pad, and the toes are short (Figure 95h). The outer toes are stout and have long bristles and short spoon-shaped bristles of uncertain function – perhaps they are used for grooming (Nowak 1999), or sexual stimulation (Rosevear 1965), or for feeling for toe-holds and obstacles especially when scuttling backwards. The toes (except first toe [hallux]) have three phalanges. Long sensory hairs project from the rumps of many species. There are no pubic nipples. The tail is relatively short to medium (27–44% of TL in African species) and, except during flight, it extends well beyond the somewhat shortened interfemoral membrane. During flight, the interfemoral membrane slides backwards so the tail is more or less fully enclosed, and the hindlimbs and calcars are able to alter the trim of this flight membrane. The tip of the tail can be waved around and is used to feel the walls and ceilings of confined spaces into which many species scuttle backwards to roost.

Molossid skulls have no striking features (such as nasal swellings and frontal shields) by which they can be recognized immediately. The rostrum ranges from moderately long to short, and the braincase is rather broad and either slightly flattened or very conspicuously flattened. There are no postorbital processes and no pronounced supraorbital ridges. The sagittal and lambdoid crests range from slightly developed to well developed. The nasal branches of the premaxillae are present; the palatal branches are sometimes present and sometimes absent. Consequently, the anterior palatal emargination can be open or closed and this is an important diagnostic character (see below). The basisphenoid bone, on the ventral surface of the braincase, has pits, which are also of diagnostic importance. The dental formula for African species is variable: $^{1123}/_{2123} = 30$, $^{1123}/_{1123} = 28$, $^{1123}/_{3123} = 32$, $^{1113}/_{3123} = 30$, or $^{1113}/_{1123} = 26$. Selected external characters of the molossids are illustrated in Figure 95. Characteristics of the dentition that are of diagnostic importance are listed below (pp. 467–471).

Molossids are widely considered to be the most highly adapted bats. The articulation of the bones in the shoulder represents an advanced condition (Vaughan 1966). The majority have high to very high aspect ratios, medium to very high wing-loadings, and wing-tips that are larger than average and slightly rounded. Consequently, these bats must fly fast and, although they have considerable agility, they have poor manoeuvrability and can only forage in open spaces (Norberg & Rayner 1987). During flight, the ears arch dorsally and resemble an aerofoil of high camber; they probably develop lift, which helps support the head during flight (Vaughan 1966). Molossids typically cannot hover or take off from the ground. They are insectivorous and, as a family, feed on many different night-flying insects. They fly high, and some species prey on nocturnal insects that migrate at high altitudes, or become concentrated in the warmer upper layers by atmospheric conditions such as temperature inversions and pressure fronts (Drake & Farrow 1988, Cotterill & Fergusson 1993b, Griffin 1995). For example, flocks of molossids in the southern USA forage as high as 3000 m (Williams *et al.* 1973), and molossids have been recorded foraging to 500 m in Zimbabwe (Fenton & Griffin 1997); no attempts have been made, as yet, to detect their presence at higher altitudes in Africa. Some molossids

Figure 95. External characters of African bats in the family Molossidae. (a) Flight membranes and bones of wing, hindlimb and tail (e.g. *Tadarida condylura*). (b) Dorsal view of partly folded right wing showing the first phalanges of the third and fourth fingers flexing dorsally: the second finger lies against the ventral surface of the third finger and is not visible in this view. Ventral views showing the interfemoral membrane and calcar (c) during cursorial locomotion or rest, and (d) during flight. (e) Ventral view of a hypothetical molossid showing an example of a mid-ventral marking and two examples of ventral flank-stripes: one showing the pelage of the stripe more or less confined to the flank; the other showing the pelage of the stripe extending onto the wing-membrane with a narrow gap between the pelage on the wing and that on the flank. Dorsal views of the head of a *Tadarida* showing (f) an interaural crest retracted into the pocket-like invagination in the interaural band, and (g) erected. (h) Dorsal view of the right hindfoot showing long sensory hairs on all toes, and spoon-hairs on the outer sides of the thicker first and fifth toes.

eat hard-shelled beetles and have thick jaws, well-developed cranial crests and fewer but bigger teeth: others eat soft-bodied insects and have correspondingly thinner jaws, lower cranial crests and more but smaller teeth (Freeman 1979, 1981). Flight for these long-and-narrow winged bats is energetically cheap, so they forage and feed by fast-hawking, and foraging flights are usually of many hours' duration. Their foraging flights are characterized by agile diving, swerving and side-slipping. The echolocation calls of molossids (at least *Tadarida* spp.) are more varied and adaptable than those of most other African bats (see order Chiroptera). While cruising and foraging, the majority of calls are short to long CF calls or shallow

linear and shallow quasi-linear FM sweeps, with maximum energy in the fundamental harmonic (Figure 96a). As a bat approaches a target, its calls become progressively broader in bandwidth, shorter and more frequent (Figure 96c and d) and may be followed by a feeding-buzz (Figure 96e and f). These sequential changes in call-shape enable bats in Africa to be recognized as molossids, but it is not yet possible to recognize (with certainty) any species of African molossid from isolated calls because there are no data for many species, and the full repertoire of calls for most species is not yet known. For some species at least, calls emitted in cluttered surroundings (e.g. near day-roosts and close to ground) are steep linear FM sweeps (Figure 96g and h)

that are very different to the search-phase calls. Echolocation calls are emitted through the mouth. The calls of some species are audible to people with unimpaired hearing of higher frequencies.

Molossids are well adapted for cursorial locomotion: they can walk slowly or scuttle as fast as a mouse over horizontal to vertical surfaces, and they can move backwards or sideways for short distances. Molossids often scuttle forwards over distances of many metres between their roosts and landing-sites, and juveniles of at least one species, *Tadarida pumila*, apparently forage by chasing non-volant insects such as cockroaches inside their day-roosts (Marshall & Corbet 1959). Like emballonurids (and to a less extent like rhinopomatids), molossids can furl their flight-membranes so the forearms and legs can move freely. When a wing is furred, the first phalanx of the third and fourth finger flexes dorsally to lie against the metacarpals, and the metacarpals (which are never longer than the radius) flex to lie snugly against the forearm. Pads on the wrists and soles, and stout muscular legs, are additional adaptations associated with regular and sustained cursorial locomotion. During the day, molossids roost in caves and cave-like day-roosts, usually tucking themselves backwards into narrow nooks and crannies. Some roost in similar confined spaces under exfoliating rocks and bark and several species also roost in the roofs of all sorts of buildings, occupied by humans or otherwise. Bats in the African genera *Platymops* and *Sauromys* are dorsoventrally flattened and can squeeze into particularly narrow spaces. Molossids cling in contact with the horizontal and/or vertical surfaces of their roost-sites. Because of their wing morphology, they need to dive to gain sufficient speed for flight, and they need to swoop upwards and stall before landing. Consequently, they can only use day-roosts with landing and take-off sites at least 1.5 m above open ground, and they must be able to scuttle from there to a suitable roost-site. Bats diving very steeply from the roof of a house are almost always molossids. Molossids are particularly vulnerable to predation from bat hawks *Macheiramphus alcinus* and other birds of prey, which learn when and where the emerging bats make their dives. Small carnivores such as genets *Genetta* can catch these bats if they have to scuttle across a roof before diving. Some molossids seem to prefer roosts with high temperatures and are found under roofs of corrugated iron where temperatures may range from 16 to 54 °C, and relative humidities from 35 to 90% (Mutere 1973a). There is no definite evidence of true hibernation in this family although some species spend short periods (e.g. up to eight days in *T. teniotis*) in a state of torpor during winter. In

some localities, molossids remain active while some of the sympatric species in other families hibernate. Most African molossids roost in small to very large groups although some individuals of some species roost singly. Little is known about their social behaviour with the exceptions of *Otomops martiensseni* and *T. pumila*, which sometimes establish harems. Molossids have many vocalizations, apparently associated with intra-specific communication, which are audible to people as squeaking and twittering. Colonies of roof-dwelling molossids become very noisy for about an hour before the bats emerge. Molossids (except extremely rarely) are monogamous. The reproductive chronologies of African species include seasonal monoestry (*Tadarida aegyptiaca*, *Otomops martiensseni*), bimodal polyoestry with postpartum oestrus (*Tadarida condylura*, *T. fulminans*), bimodal polyoestry without postpartum oestrus (*T. condylura*, *T. thersites*) and multimodal polyoestry with postpartum oestrus (*T. pumila*). There is a trend (exemplified even intra-specifically by *T. pumila*) towards bimodal polyoestry or multimodal polyoestry and extended or well-separated parturition seasons in equatorial regions, with fewer litters/year crowded into progressively shorter reproductive seasons at higher latitudes (Happold & Happold 1990b, Bernard & Cumming 1997). Reproductive delays are not known to occur in African molossids. Neonates (for which data are available) are naked, relatively large and they develop rapidly. They are left in crèches while their mothers forage.

The geological range of the family Molossidae is late Eocene to Recent in Europe and North America, late Oligocene to Recent in South America, middle Miocene to Recent in Africa and Australia, and Pleistocene to Recent in Asia and the East and West Indies (Koopman 1984, Hand 1990). The late Eocene molossids from Europe are slightly younger than those from North America. Three different areas of origin have been suggested for this family: the Neotropics, Africa and the Indo-Australian region (Freeman 1981). Simmons (1998) concluded, from cladistic analysis of 192 morphological and molecular characters, that they most likely originated in the Neotropics.

Molossids have radiated into forests, savannas and bushlands, semi-deserts and deserts. Of the 34 species in Africa, 26 are found almost entirely in the tropics. Seven other species are mainly tropical but also extend southwards into temperate habitats (and one of these also extends northward into temperate habitats). There is also one Palearctic species, which, in Africa, is found only in temperate habitats in North Africa. Of the 32 species for which data are available, 13 are found

Figure 96. Sonograms of echolocation calls of two molossids from Malawi, showing the diversity of calls made in different situations (M. Happold unpubl.). (a) and (b) Search-phase calls of *Tadarida condylura*, emitted during foraging or cruising in open space high above ground. (c) and (d) Approach-phase calls of *T. condylura*, emitted during foraging high above the ground. (e) and (f) Consecutive calls from a 'feeding buzz' emitted by *T. condylura*. (g) and (h) Consecutive calls emitted by a bat, *Tadarida pumila*, as it dived to gain sufficient speed for flight after taking off from about 3 m above ground. (i) Search-phase call emitted by another individual, *T. pumila*, while foraging/cruising in open space far above ground. (j), (k) and (l) Non-consecutive approach-phase calls from a sequence (see Figure 27) emitted by *T. pumila*. Time axis marked at intervals of 10 ms.

mainly in woodland savannas, five are found in woodland savannas and extend into arid grassland savannas (and one of these also extends into desert habitats in the South-West Arid BZ), six are found mainly in rainforest, six in forest–savanna mosaics near the northern edge of the rainforest, one (*Tadarida bemmeleni*) is found in rainforest (*T. b. bemmeleni*) and in savannas and rainforest–savanna mosaics (*T. b. cistura*), and one is found in Mediterranean habitats. Only one species (*Sauromys petrophilus*) seems close to being a desert specialist. Only 12 species (36%) have been collected in montane habitats (although this might reflect inadequate sampling) but others possibly forage over montane habitats without roosting there. Most localities are probably exploited by more than one species, for example:

Kikwit, DR Congo (rainforest): *Myopterus whitleyi*, *Tadarida ansorgei*, *T. condylura*, *T. nanula*, *T. niveiventer*, *T. pumila* and *T. thersites* (Van Cakenberghe *et al.* 1999).

Sengwa Wildlife Research Area, Zimbabwe (miombo and mopane woodland): *Otomops martiensseni*, *Tadarida aegyptiaca*, *T. ansorgei*, *T. chapini*, *T. fulminans* and *T. nigeriae* (Fenton 1985).

Because molossids are difficult to capture, there are undoubtedly immense gaps in our knowledge of their habitat preferences and distributions.

The taxonomy of the family Molossidae is controversial. Based on morphological data, Simmons (1998) placed the Molossidae in the superfamily Molossoidea together with the New World family Antrozoidae, and she recognized two subfamilies, the Tomopeatinae in the New World and the Molossinae, which has representatives in Africa. Koopman (1993, 1994) placed the Tomopeatinae in the Vespertilionidae, and consequently does not recognize any subfamilies in the Molossidae. Recent studies, based on molecular data, contradict some of the groupings based on morphological data and therefore, pending further studies, no chiropteran superfamilies are recognized by Simmons (2005). The subfamilies Tomopeatinae and Molossinae are recognized by Simmons (2005); the subfamily Tomopeatinae is represented by only one species *Tomopeus ravs* that is found in Peru, and the subfamily Molossinae includes all other molossids. Based on dental morphology, Legendre (1984) divided the family Molossidae (not including *Tomopeus*) into three subfamilies: the Molossinae (including *Myopterus* from Africa and six genera from the New World), the subfamily Cheiromelinae (including one genus from South-East Asia) and the subfamily Tadarinae (including *Tadarida* [including *Chaerephon* and *Mops*], *Mormopterus* [including *Platymops* and *Sauromys*] and *Otomops*), all of which are represented in Africa, and also *Nyctinomops* (from the New World) and *Rhizomops* (treated as a synonym of *Tadarida* by Simmons 2005). Pending resolution of inter-generic relationships, no divisions of the family Molossidae are recognized by Simmons (2005), or here, except for the subfamilies Molossinae and Tomopeatinae. Neither subfamily is profiled below because differences between them are not relevant to this account, which is restricted to African molossids in the subfamily Molossinae.

Opinions also differ (and change) about the generic versus subgeneric status of several taxa including *Chaerephon*, *Mops*, *Xiphonycteris*, *Platymops* and *Sauromys*, which are represented in Africa. Pending further studies, *Platymops* and *Sauromys* are recognized here as distinct genera (although they are considered subgenera of *Mormopterus* by some authors). It seems probable that *Chaerephon* and *Mops* are not

monophyletic and, pending revision, these taxa and *Xiphonycteris* are retained here in *Tadarida* (*contra* Simmons 2005). For further details, see genus and species profiles.

The six genera recognized here, which occur in Africa, can be distinguished by the combination of characters given in Table 19, p. 472. The characters that are most useful as the means of distinguishing the genera, and also species within the genus *Tadarida sensu lato*, include the following:

Inner margins of ears. Can be (a) well separated, (b) meeting to form a V-shaped valley (as a result of the bases being close but not joined or only just joined), (c) forward-projecting and joined to forehead and muzzle, or (d) wide apart but well joined across forehead by a broad band of skin and cartilage (Figure 97).

Folding of ears. The ears can be with or without complex folding, or with moderate folding (Figure 97).

Relative size of ears. Described as small (extending about half-way along muzzle when laid forward) to large (extending well beyond snout when laid forward).

Interaural crest. Can be present or absent, long and bicoloured (Figure 112) or short and unicoloured (Figure 95).

Dorsal pelage. Varies in colour; can be striped, spotted, flecked or uniform in colour. Dorsal hairs can be unicoloured or bicoloured.

Mid-ventral markings. Can be present or absent. Markings include a stripe or a patch or several patches, in contrasting pale colour (Figure 95e).

Ventral flank-stripe in contrasting colour. Can be present or absent. Refers to the narrow band of pelage running along the ventral boundary between the wing-membrane and the body and sometimes extending marginally onto the wing-membrane; its hairs are sometimes longer than hairs of the adjacent ventral pelage (Figure 95e). This band of pelage can be the same colour as the adjacent ventral pelage (and therefore a ventral flank-stripe in contrasting colour is absent), or its colour can contrast with the adjacent ventral pelage, in which case it is usually much paler or white, but it is sometimes black and much darker.

Colour of wing-membranes. Can be black, white, various shades of brown or grey, or almost colourless and transparent. In some species, the dorsal and ventral surfaces differ in colour.

Upper lip. Can be smooth, or with fine microscopic wrinkles, or with a number of conspicuous vertical wrinkles. The number of wrinkles is the number of raised ridges (not the number of valleys). The upper lip can have many short, thick, spatulate hairs known as spoon-hairs, or few spoon-hairs, or no spoon-hairs.

Gular gland (sometimes in gular sac). Can be present or absent.

Plantar pad. A raised pad on the sole of the foot, which can be present or absent.

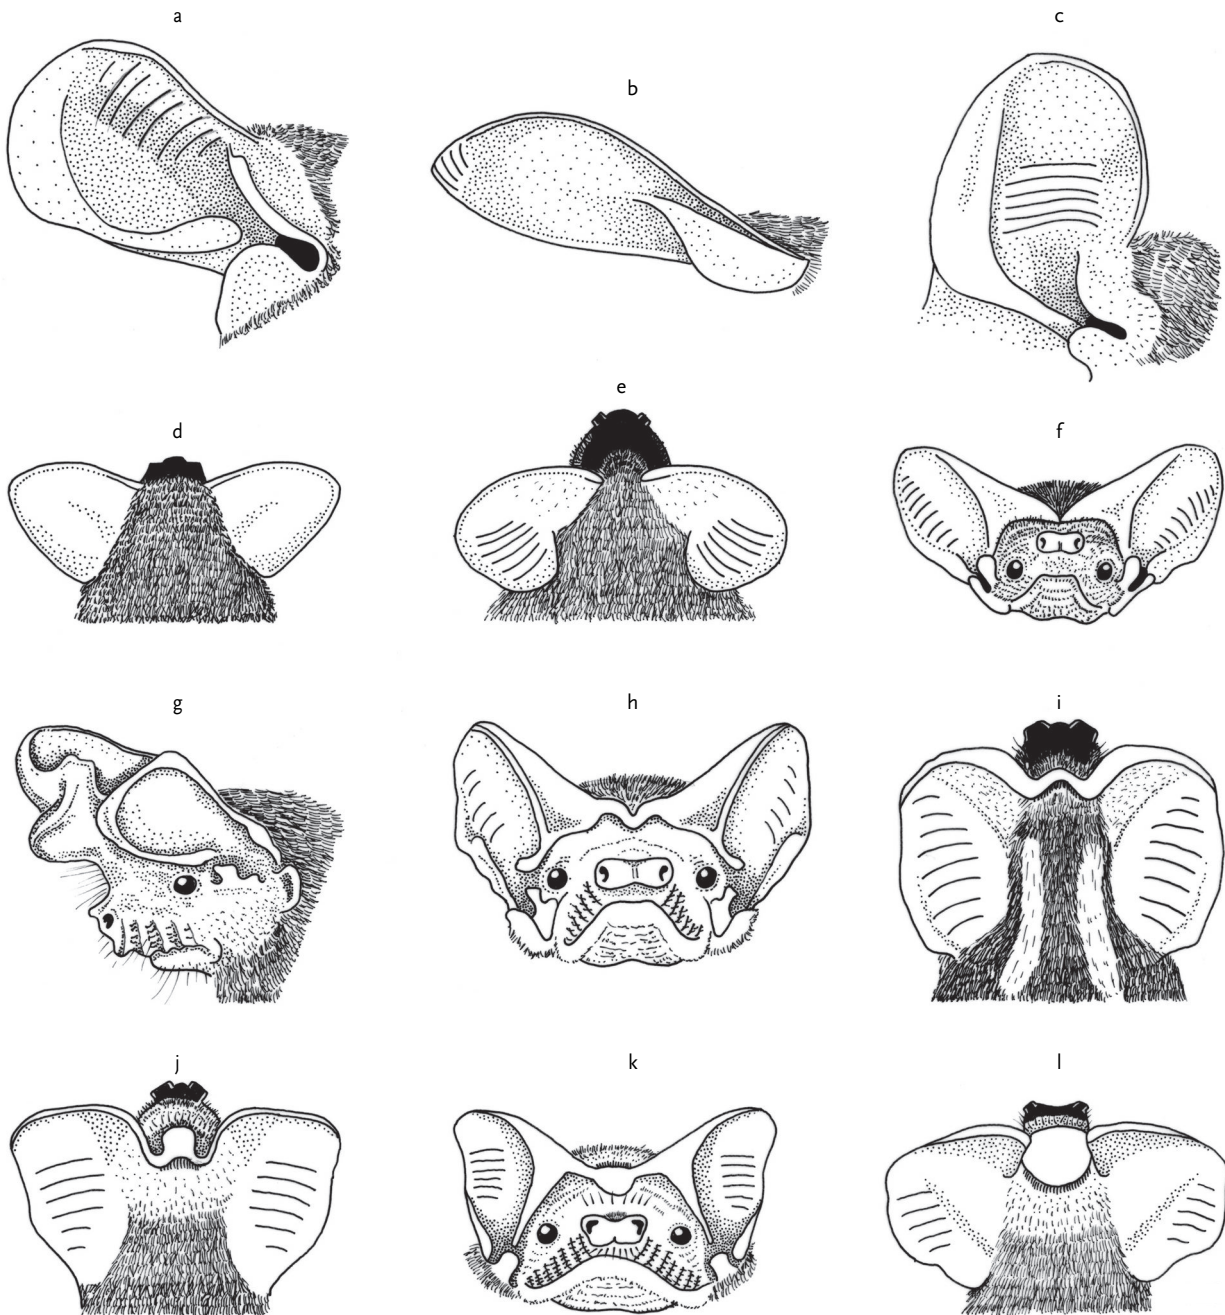

Figure 97. Variations in the ears of African bats in the family Molossidae. Ears that (a) have complex folding (e.g. *Tadarida aloysiisabaudiae*; based on photo by J. Fahr), (b) have moderate folding (*Otomops martiensseni*; after Smithers 1983) and (c) do not have complex folding (e.g. *Myopterus daubentoni*; based on photo by J. Fahr). Ears that are (d) well separated (e.g. *Platymops setiger*; based on photo in Harrison & Fleetwood 1960), (e) separated by narrow gap (*Sauromys petrophilus*; based on photo in Mills & Hes 1997), (f) meeting to form a V-shaped valley (e.g. *Tadarida lobata*; based on Peterson & Harrison 1970), (g) forward-projecting and joined to forehead and muzzle (*T. gallagheri*; based on Harrison 1975), (h) and (i) wide apart but well joined across forehead by an interaural band with V-shaped fold (e.g. *T. bivittata*; based on Eger & Peterson 1979), (j) and (k) joined by interaural fold with backward-opening pocket-like invagination in middle (e.g. *T. condylura*), (l) lappet-eared (*T. major*). Within most of these categories, there are considerable inter-specific variations.

Degree of flattening of the skull. The skull (and head) can be extremely flattened dorsoventrally or not extremely flattened. In the latter category, the skull can be low but not extremely flattened in some species (Figure 98).

Anterior of braincase. Can be not noticeably elevated, slightly elevated, moderately elevated or prominently elevated above the plane of the rostrum (Figure 99).

Sagittal and lambdoid crests. Can be absent, or poorly developed to well developed.

Anterior palatal emargination. Can be closed (non-existent), or deep (reaching to mid-canine level or a little further posteriorly), very narrow, narrow or wide, and can be U-shaped or bulb-shaped (Figure 100). When the palatal emargination is closed, a pair of palatal foramina is usually present.

Figure 98. Skulls of African Molossidae showing different degrees of dorsoventral flattening: (a) extremely flattened (e.g. *Sauromys petrophilus*; ZFMK 77.489), (b) not extremely flattened but low (e.g. *Tadarida aegyptiaca bocagei*; BMNH 23.5.9.27), (c) not extremely flattened (e.g. *T. brachyptera leonis*; BMNH 92.10.6.3).

BELOW: Figure 99. Skulls of African *Tadarida* showing inter-specific differences in the elevation of the braincase above the plane of the rostrum. Braincase prominently elevated, as in (a) *Tadarida gallagheri* (holotype; after Harrison 1975) and (b) *Tadarida petersoni* (holotype; based on El-Rayah 1981). Braincase moderately elevated, as in (c) *Tadarida midas* (BMNH 22.12.17.99) and (d) *Tadarida bivittata* (BMNH 75.2674). Braincase slightly elevated, as in (e) *Tadarida ansorgei* (BMNH 66.3613) and (f) *Tadarida pumila* (RMCA 97-21-M-731). Braincase very slightly elevated or flat as in (g) *Tadarida nanula* (RMCA RG 19839) and (h) *Tadarida aegyptiaca* (BMNH 23.5.9.27).

Figure 100. Shapes of the anterior palatal emargination found in African Molossidae. (a) Closed with incisive foramina visible (e.g. *Tadarida niveiventris*). (b) Narrow and separated from incisive foramina by bony bar (e.g. *T. pumila*). (c) Narrow and not separated from incisive foramina, which retain only a remnant of the bony septa between them (e.g. *T. pumila*). (d) Bulb-shaped (e.g. *T. bivittata*). (e) Narrow (e.g. *T. thersites*). (f) Wide (e.g. *T. fulminans*). (g) Very narrow and deep (*Otomops martiensseni*).

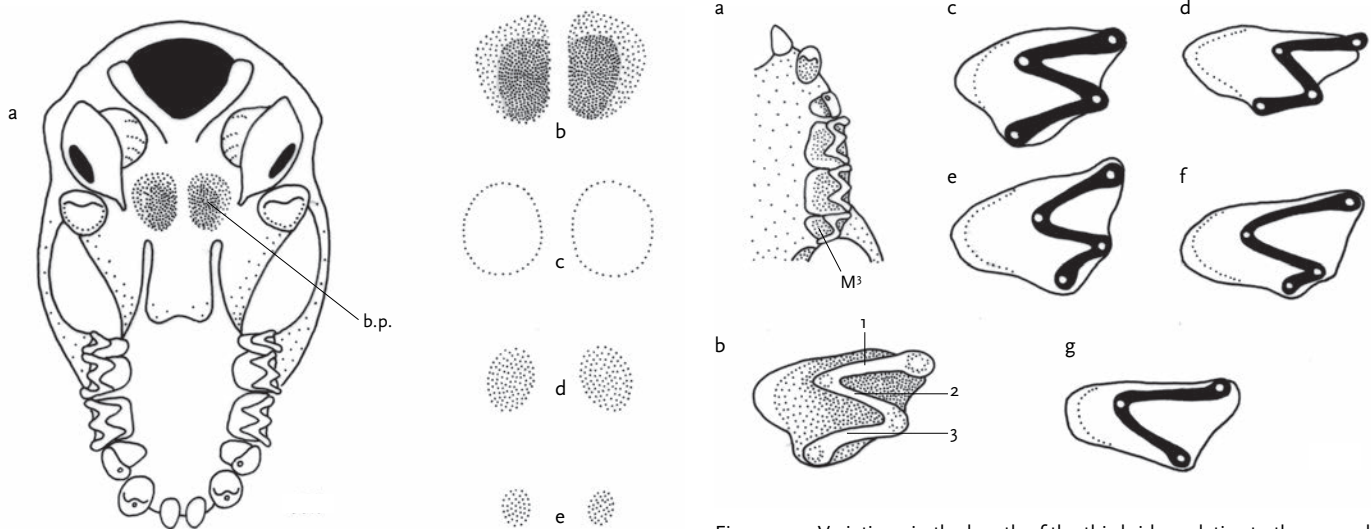

Figure 101. Variations in the depth and relative size of the basisphenoid pits of African Molossidae. (a) Ventral view of skull showing position of basisphenoid pits (b.p.). (b) Pits very deep and relatively large – width of each pit much greater than distance between pits (e.g. *Myotis whitleyi*). (c) Pits shallow and relatively large (e.g. *Mormopterus francoismoutoui*). (d) Pits moderately deep and of medium relative size – width of each pit about same as distance between pits (e.g. *Tadarida lobata*). (e) Pits moderately deep and relatively small – width of each pit noticeably less than distance between pits (e.g. *Tadarida petersoni*). The skulls from which each pair of pits was drawn were enlarged to the same mastoid width.

Basisphenoid pits. These are a pair of pits (one on each side) located in the basisphenoid bone on the ventral surface of the braincase (Figure 101a); they can be absent, shallow, moderate, deep or very deep (assessed qualitatively; most data from Freeman 1981) and they can be relatively large (width of pit noticeably > distance [septum] between pits), medium (width of pit ca. = distance between pits), or

Figure 102. Variations in the length of the third ridge relative to the second ridge of M^3 , the third upper molar, in *Tadarida*. (a) Left upper tooththrow showing M^3 . (b) Left M^3 with ridges one, two and three labelled. (c) Third ridge > second ridge. (d) Third ridge = second ridge. (e) Third ridge > half of second ridge. (f) Third ridge < half of second ridge. (g) Third ridge absent.

small (width of pit noticeably < distance between pits) (Figure 101c, d and e, respectively).

Length of third ridge relative to length of second ridge of M^3 , the posterior upper molar. The third ridge (the most posterior ridge) can be (a) equal in length or slightly longer than the second, (b) equal to the second, (c) more than half of the second but never equal to it, (d) less than half of the second but not completely absent or (e) absent (Figures 102c–g, respectively).

Anterior upper premolar. Can be distinctly shorter than the cingulum of the posterior premolar, and either displaced labially or in tooththrow,

Figure 103. Sizes of the anterior upper premolar relative to the height of the cingulum of the posterior premolar, and its position. *Left*: occlusal views of teeth on left side of upper jaw. *Right*: lateral views of labial side of the same teeth. (a) Anterior upper premolar distinctly shorter than the cingulum of the posterior premolar and displaced labially (e.g. *Tadarida condylura*). (b) Anterior upper premolar distinctly shorter than cingulum of posterior premolar and in tooththrow (e.g. *T. major*). (c) Anterior upper premolar approximately same height as cingulum of posterior premolar and in tooththrow (e.g. *Sauromys petrophilus*). (d) Anterior upper premolar distinctly taller than cingulum of posterior premolar and in tooththrow (e.g. *T. aloysiisabaudiae*). (e) Anterior upper premolar absent (e.g. *Myopterus whitleyi*).

ca. same height as cingulum of posterior premolar, distinctly taller than cingulum of posterior premolar, or absent (Figures 103a–e, respectively).

Upper incisors. Can be procumbent (angled forward), or not procumbent (pointing downwards and/or somewhat inwards) (Figures 104a and b, respectively).

Figure 104. The upper incisors of *Tadarida* can be procumbent or not procumbent. (a) Lateral and occlusal views of the procumbent upper incisor in *Tadarida nanula* that is not obscured by the canine cingula. (b) Lateral and occlusal views of the non-procumbent upper incisor in *T. spurrelli* that is, in this specimen, almost entirely obscured by the canine cingula. Incisors shown in solid black; both specimens are ♂♂.

Figure 105. Lower incisors and canines of African *Tadarida*. (a) Canine cingula not greatly enlarged and not in contact; incisors crowded (e.g. *T. aegyptiaca*). (b) Canine cingula greatly enlarged and in contact; incisors reduced in number and crowded (*T. spurrelli* ♂).

Lower incisors. There can be one, two or three on each side, and they can be crowded by the cingula of the lower canines, or not crowded (Figure 105).

Lower canines. The cingula are always large and conspicuous compared with bats in other families but, in some species of molossids, they are greatly enlarged (Figure 105). The cingula are often larger in ♂♂ than in ♀♀ of the same species.

The six genera represented in Africa are presented in alphabetical order.

Meredith Happold & F. P. D. Cotterill

Table 19. Key to the African genera in the family Molossidae (based on African species only). For details of the differences in these characters, see Family Molossidae.

| Head and skull | Inner margins of ears
(Folding of ears) | Length of
third ridge (3)
in relation to
second ridge
(2) of posterior
upper molar
(M ³) | Miscellaneous | Genus |
|---|---|--|---|--|
| Extremely flattened | Widely separated
(Without complex folding) | $3 = 2$ | Forearm with warty granulations
FA: 27–36 mm
Upper lip with many fine wrinkles and many stiff bristles | <i>Platymops</i>
(1 species) |
| Extremely flattened | Meeting to form V-shaped valley
(Without complex folding) | $3 = 2$ | Forearm without warty granulations
FA: 37–50 mm
Upper lip smooth with only a few stiff bristles | <i>Sauromys</i>
(1 species) |
| Low but not extremely flattened | Distinctly separated or almost touching
(Without complex folding) | $3 \geq 2$ | Forearm without warty granulations
FA: 38–43 mm
Ears never white or translucent
Upper lip with many well-defined wrinkles but few spoon-hairs | <i>Mormopterus</i>
(1 or 2 species) |
| Not extremely flattened but sometimes low | Meeting (or almost meeting) to form V-shaped valley
or
Joined by band
(With complex folding) | Varied:
$3 = 2$
$3 > \text{half } 2$
$3 < \text{half } 2$
3 absent | FA: 27–67 mm
Ears never white or translucent
Ears 10–33 mm
Sometimes with yoke of almost naked, pale skin across nape of neck
Upper lip usually with well-defined wrinkles and many spoon-hairs | <i>Tadarida</i>
(27 species) |
| Low but not extremely flattened | Widely separated
or
Meeting to form V-shaped valley
(Without complex folding) | 3 absent | FA: 35–54 mm
Ears whitish or translucent
Ears 14–22 mm
Upper lip smooth with many spoon-hairs | <i>Myopterus</i>
(2 species) |
| Low but not extremely flattened | Forward-projecting and joined to forehead and along extended muzzle
(With moderate folding) | $3 \leq 2$ | FA: 61–74 mm
Band of dense white or pale pelage across top of shoulders and along flanks
Dorsal hairs conspicuously bicoloured
Ears very long (31–42 mm)
Upper lip with fine, microscopic wrinkles and no spoon-hairs | <i>Otomops</i>
(1 species) |

GENUS *Mormopterus*

Little Mastiff Bats and others

Mormopterus Peters, 1865. Monatsber. K. Preuss. Akad. Wiss. Berlin 1865: 258. Type species: *Nyctinomus (Mormopterus) jugularis* Peters, 1865.

Mormopterus was considered to contain ten species (Simmons 2005) but another species, *M. francoismoutoui*, has been described by Goodman *et al.* (2008). Species of *Mormopterus* include *M. acetabulosus* from Mauritius and *M. francoismoutoui* from Réunion, at least one of which has been recorded in Africa (but probably only as vagrants), and *M. jugularis* from Madagascar, which presumably has the potential to reach Africa as a vagrant although it has not yet been recorded there. The other species occur in the Malay archipelago, South America, Cuba or Australia. There are about seven more undescribed species in Australia (Churchill 1998). *Mormopterus* is included in *Tadarida* by some authors including Freeman (1981), but considered distinct by Legendre (1984), Meester *et al.* (1986), Corbet & Hill (1991, 1992) and others. *Mormopterus* is sometimes considered to include *Platymops* and *Sauromys* (e.g. Koopman 1993, 1994) but these genera are currently considered

distinct (Corbet & Hill 1992, Peterson *et al.* 1995, Simmons 2005). The only three species of *Mormopterus* likely to be recorded in Africa are distinguished from species in other molossid genera in Africa by the following combination of characters: head, body and skull low but not extremely flattened (cf. *Platymops* and *Sauromys*); ears black and not translucent (cf. whitish or translucent in *Myopterus*); inner margins of ears distinctly separated although close; third ridge of posterior upper molar (M³) equal in length or longer than second ridge; anterior palatal emargination wide; four upper cheekteeth on each side (cf. five in *Tadarida* except rarely); three lower incisors on each side (cf. one in *T. spurrelli*, two in all other African *Tadarida* except *T. teniotis*, which also has three; see also Table 19, p. 472). Dental formula (*M. acetabulosus*, *M. francoismoutoui*, *M. jugularis*): $\frac{1113}{3123} = 30$. Craniodental characters of *Mormopterus* are illustrated in Figure 106.

When the *Mormopterus* profiles were submitted, only two specimens of one species – *M. acetabulosus* – were said to have been recorded from Africa; one from Ethiopia and one from South Africa. Now, the Ethiopian specimen has been re-identified as *M. francoismoutoui* but the identity of the South African specimen could not be confirmed because its skull is missing: it could represent either *M. acetabulosus* or *M. francoismoutoui* (Goodman *et al.* 2008). Information about both species and the two African specimens is included in the following profile.

Meredith Happold

Figure 106. Skull of *Mormopterus francoismoutoui* (BMNH 6.11.1.9 from Ethiopia). This specimen was previously considered to represent *M. acetabulosus* (Goodman *et al.* 2008).

***Mormopterus acetabulosus* and *M. francoismoutoui* MAURITIAN LITTLE MASTIFF BAT AND RÉUNION LITTLE MASTIFF BAT**

Fr. Mormoptère à lèvres ridées; Ger. Mauritius Mastino-Fledermaus, Réunion Mastino-Fledermaus

Mormopterus acetabulosus (Hermann, 1804). Observ. Zool. p. 19. Port Louis, Mauritius. For several reasons, Goodman *et al.* (2008) designated FMNH 1984.368, from Palma Cave, Palma, Black River District, Mauritius, 20° 16.405' S, 57° 27.147' E, as the neotype of this species.

Mormopterus francoismoutoui Goodman, van Vuuren, Ratrimomonarivo, Probst & Bowie, 2008. J. Mammal. 89: 1318. Commune de La Possession, Pont de Balthazar, 2.2 km SSW La Possession, La Réunion, 20° 56.732' S, 55° 19.484' E, 40 m.

Taxonomy *Mormopterus acetabulosus* was originally described as *Vespertilio acetabulosus*. Until recently, it was thought to occur mainly on Mauritius and Réunion, but with two specimens (probably vagrants) recorded from Africa. However, based on both molecular and morphological evidence, specimens from Mauritius and Réunion are now considered specifically distinct and the Réunion bats have been described as a new species, *Mormopterus francoismoutoui* (Goodman *et al.* 2008) (details in Appendix). Of the two specimens from Africa, one (BM 6.11.1.9 from Ethiopia) is considered by these authors to represent *M. francoismoutoui*. The other (MNHN 1984-201 from 'Port Natal' [now Durban]) is in poor condition and its skull could not be located: consequently Goodman *et al.* (2008) could not ascertain if it represents *M. acetabulosus* or *M. francoismoutoui*. Synonyms: *natalensis*. Subspecies: none. Chromosome number: not known.

Description Very small microbats without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid; head and body not extremely flattened; ears separated and without complex folds, upper

lip with many well-developed wrinkles; wings dark; forearms without warty granulations; anterior upper premolar absent. Sexes similar. Pelage short (mid-dorsal hairs 3–4 mm). Dorsal pelage uniformly dark brown; hairs unicoloured. Ventral pelage dark brown becoming slightly paler on abdomen. Head somewhat (but not extremely) flattened. Upper lip with many (>7) well-developed wrinkles, a few spoon-hairs and many fine hairs. Ears relatively short, erect, widely separated (by 2–4 mm) in *M. acetabulosus*, almost touching and joined by a slender band of skin in *M. francoismoutoui*, subtriangular with slight emargination below tip, without complex folds (cf. *Tadarida*). Tragus small but not concealed by antitragus. Antitragus low, indistinct. No interaural crest. Gular gland present in ♂♂. Wings and interfemoral membrane dark brown. No wart-like granulations on forearm. Hindfeet relatively large; toes with long hairs and many short, stout bristles.

Skull (Figure 106) low but not extremely dorsoventrally flattened (cf. *Platymops* and *Sauromys*) (maximum height ca. 41% of GLS as in *Tadarida pumila*). Rostrum relatively narrow (cf. *Platymops*). Zygomatic arches slender. Anterior of braincase rising above plane of rostrum; forehead slightly concave. Sagittal crest low or absent; lambdoid crest

low or absent. Lachrymal ridges indistinct and forming a comparatively small tubercle on each side of rostrum (cf. *Platymops*). Anterior palatal emargination wide. Basisphenoid pits shallow, much wider than their distance apart. Upper incisors well separated. Anterior upper premolar absent. M^3 with third ridge \geq second ridge (Figure 102c and d). Three lower incisors on each side. Lower canines with cingula not greatly enlarged and not in contact. Dental formula: $1^{113}/_{3123} = 30$.

Geographic Variation None recorded for either *M. acetabulosus* *sensu* Goodman *et al.* (2008) or *M. francoismoutoui*.

Similar Species Four other African molossids have ears without complex folds:

Myopterus daubentonii. Much larger (FA: 48–56 mm; GLS: 21.3–25.7 mm). Dorsal pelage with contrasting lateral bands of paler colour. Wings with arm-wing white, hand-wing transparent. M^3 with third ridge absent.

M. whitleyi. Forearm shorter (35–37 mm); skull larger (GLS: 16.6–18.5 mm). Arm-wing yellowish-white, hand-wing transparent. M^3 with third ridge absent.

Platymops setiger. Head extremely flattened. Forearms with warty granulations. Skull with very prominent lachrymal ridges.

Sauromys petrophilus. Inner margins of ears separated by narrow gap. Head extremely flattened. Anterior upper premolar present.

Distribution One specimen (of uncertain identity according to Goodman *et al.* 2008) was recorded in 1933 from Durban, KwaZulu–Natal, South Africa in the Coastal Forest Mosaic BZ, and one specimen (identified with *M. francoismoutoui* by Goodman *et al.* 2008) was recorded in 1905 from Ethiopia (between L. Turkana and Shewa Province), presumably in the Afromontane–Afroalpine BZ of the Ethiopian Highlands. Extraliminally: Mauritius and Réunion (but see Taxonomy). *Mormopterus acetabulosus* was said to occur

on Madagascar (e.g. Hayman & Hill 1971, Kingdon 1974, 1997, Koopman 1993) but no valid specimen appears to be available and the inclusion in Madagascar apparently arises from the confusion of names listed in synonymy dating back to Peters (1865), who proposed that the subgenus *Mormopterus* includes taxa from South Africa, Madagascar and the Mascarene Is. (Peterson *et al.* 1995). The lack of further records from Africa suggests that the African records are those of vagrants and that *Mormopterus* does not normally occur on the mainland. A specimen of ‘*Mormopterus* sp.’ (FA: 32 mm) from Meru N. P. (Webala *et al.* 2004) does not represent *M. acetabulosus* or *M. francoismoutoui* (M. Happold pers. obs.).

Habitat Recorded from the edge of a forest near Durban (Smithers 1983); no data for the Ethiopian locality. On Réunion, *M. francoismoutoui* is widespread and found from sea level to ca. 2000 m.

Abundance Only two specimens recorded in Africa. *Mormopterus francoismoutoui* appears common on Réunion.

Remarks On Réunion, *M. francoismoutoui* roosts in caves, crevices in rockfaces, and similar sites in bridges and buildings (Goodman *et al.* 2008). Anciaux de Faveaux (1984) catalogued a mite (*Ewingana lamoralis* [Acari: Myobiidae]) from a Kenyan specimen said to represent *M. acetabulosus*, but the identity of the specimen has not been confirmed. Apparently nothing else is known about *Mormopterus* in Africa.

Conservation IUCN Category (*M. acetabulosus*): Vulnerable (based on data from Mauritius and Réunion).

GENUS *Myopterus* Winged-mouse Bats

Myopterus Oken, 1816. Lehrbuch der Naturgeschichte, pt 3 sect. 2: 932. Type species: *Myopterus senegalensis* Oken, 1816 (not available).

Myopterus E. Geoffroy, 1818. Description de l’Egypte 2: 113. Type species: *Myopterus senegalensis* Oken, 1816
(not available = *Myopterus daubentonii* Desmarest, 1820).

Myopterus (including *Eomops* as a synonym) is a polytypic genus with two species, endemic to tropical Africa from Senegal in the West to DR Congo and Uganda in the East, occurring in both rainforests and moist savannas. Distinguished from other genera of molossids in Africa by the following combination of characters: head, body and skull low but not extremely flattened dorsoventrally (cf. *Platymops* and *Sauromys*), wings translucent or whitish, ears whitish or translucent, without complex folding, either widely separated or meeting medially to form V-shaped valley; upper lip smooth with many spoon-hairs; third ridge of posterior M³ absent; dental formula: $^{1113}/_{1123} = 26$ (see also Table 19, p. 472). Bats in this genus also have white ventral pelage;

relatively short, narrow and erect ears; a large tragus (not concealed by the antitragus); upper incisors in contact; only one upper premolar on each side; one pair of lower incisors; anterior palatal emargination closed; and deep basisphenoid pits (distinct hole >1 mm in depth). Selected characters of a representative of the genus are illustrated in Figure 107, but there are some inter-specific differences. The savanna-dwelling species *M. daubentonii* is much larger than *M. whitleyi*, which is restricted to the rainforest zone. The latter species is one of the smallest molossids in Africa. In collections, both species are among the rarest African molossids. Almost nothing is known about their biology. They have been rarely captured except from their day-roosts,

Figure 107. *Myopterus*. Flight membranes of *M. daubentonii*. Unique dorsal pelage markings of *M. daubentonii*. Skull of *M. whitleyi* (RMCA 97-021-M-0825).

which are sometimes rather unusual for molossids as *M. whiteyi* has been found roosting, unconcealed, in vegetation.

In her study of the family Molossidae, Freeman (1981) found phenetic similarity between *Myotis* and the Neotropical genera *Molossops*, *Neoplatymops* and *Cynomops*. According to her study, *Myotis* is one of the most derived molossid genera and the most derived of all African molossids. Freeman (1981) speculated that *Myotis* has no extant relative in the Old World but rather a Neotropical origin, with *Molossops* and *Cynomops* being the most closely related genera. Likewise, based on dental characters, Legendre (1984) would place *Myotis* in the subfamily Molossinae, which in his arrangement

comprises otherwise New World genera, whereas all other molossid genera occurring in Africa would be included in the subfamily Tadaridinae. In a recent cladistic analysis by Jones *et al.* (2002), *Myotis* grouped with the Asian *Cheiromeles* and Neotropical *Molossops*, again without any close relationship to African molossids.

The two species are:

M. daubentonii. FA: 48–56 mm; GLS: 21.3–25.7 mm; WT: 20–22 g.

M. whiteyi. FA: 35–37 mm; GLS: 16.6–18.5 mm; WT: 10–12.0 g.

Jakob Fahr

Myotis daubentonii DAUBENTON'S WINGED-MOUSE BAT

Fr. Myoptère de Daubenton; Ger. Daubentons Pergamentflügel-Fledermaus

Myotis daubentonii Desmarest, 1820. Encyclopédie Méthodique Mammalogie 1: 132. Senegal (no specified locality).

Taxonomy Synonyms: *albatus*. Subspecies: two. The taxonomic identity of this bat has been debated for a long time (Rosevear 1965). A specimen from Senegal was described by Daubenton (1765) and named 'rat-volant', which is not a proper binomial name. Based on the description of Daubenton, it was renamed *Myotis senegalensis* by Oken (1816) and the specimen was examined by Peters (1869). The holotype was subsequently lost and therefore Brosset & Vuattoux (1968) designated a new 'type' and 'cotype' based on specimens from Côte d'Ivoire. Hill (1969) pointed out that the name *senegalensis* was not available and referred the specimens from Côte d'Ivoire to *M. albatus* Thomas, 1915, at that time known from two localities in DR Congo. Finally, Adam *et al.* (1993) designated one neotype and four neoparatypes for *M. daubentonii* Desmarest, 1820, a name that was also based on the 'rat-volant' of Daubenton, from a series collected in Senegal. They synonymized *M. albatus* as a subspecies of *M. daubentonii*, referring specimens from Côte d'Ivoire and Central African Republic to *M. d. albatus*, while restricting the nominate form, *M. d. daubentonii*, to the Senegal population (but see Geographic Variation). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid (FA: 48–54 mm); head not flattened; ears meeting on forehead to form V-shaped valley and without complex folds, inner side whitish; upper lip smooth; dorsal pelage usually with longitudinal banding, wings partly white and partly colourless and transparent. Sexes similar in colour; ♀♀ on average slightly larger than ♂♂. Pelage short (mid-dorsal hairs 4–5 mm). Dorsal pelage dark cream, reddish-brown or greyish-brown usually with two lateral bands of whitish or pale yellowish-fawn on each side of the mid-dorsal line (Figure 107); hairs (except those of bands) whitish or cream-coloured with darker tip. Crown and nape with large patch of same colour as the lateral bands. Ventral pelage uniformly dirty- or creamy-white to pure white, much paler than, and conspicuously contrasting with, the dorsal pelage; no mid-ventral markings; ventral flank-stripe same colour as flanks. Head not dorsoventrally flattened; muzzle subcylindrical, smooth and rounded, almost naked except for dense

patch of spoon-hairs on upper lip below nostrils; upper lip smooth. Ears erect (without complex folds), narrow, with outer side partly pigmented and inner side whitish; bases of inner margins meeting on forehead to form V-shaped valley. Tragus relatively very large for a molossid, simple, anterior and posterior margins nearly parallel, tip rounded; not concealed by antitragus. Antitragus semi-circular, ca. same size as tragus. No interaural crest. No gular gland. Wings with arm-wing membranes white and hand-wing membranes strikingly transparent and showing red veining and some enclosed white spots of fat. Wing-membranes of living bats feel moist and somewhat sticky. Interfemoral membrane dorsally pale brown, ventrally white. Skin of forearm, tibia, fingers and tail pink.

Skull large and robust; not extremely dorsoventrally flattened. Sagittal and lambdoid crests absent or weakly developed. Anterior palatal emargination closed. Basisphenoid pits very deep, large, their width much greater than their distance apart. Upper incisors in contact. Anterior upper premolar absent. M³ with third ridge absent. Only one lower incisor on each side, bicuspid (inner cusp distinctly higher than outer cusp), not crowded. Lower canines with cingula not greatly enlarged, well separated. Dental formula $\frac{1113}{1123} = 26$.

Geographic Variation Two subspecies are recognized (Adam *et al.* 1993), but variability seems to be high in this species:

M. d. daubentonii. Originally considered to be restricted to Senegal (Adam *et al.* 1993), but a re-examination and comparison of published data with data from new specimens from Côte d'Ivoire show that the dimensions of specimens from Senegal, Côte d'Ivoire and Central African Republic overlap sufficiently to justify assigning all of them to the nominate subspecies. FA: 50.4 (48–54) mm; TL: 110.9 (104–120) mm; GLS: 22.5 (21.3–24.9) mm; GWS: 13.4 (13.0–14.5) mm (see Measurements).

M. d. albatus. Considered to include all populations east of Senegal by Adam *et al.* (1993), but considered here to include only specimens from DR Congo, which are clearly larger than those from Senegal to Central African Republic. For five ♀♀ from Niangara, DR Congo, FA: 53.7 (52–56) mm; TL: 126.0 (123–132) mm; GLS: 25.2 (24.2–25.7) mm; GWS: 14.5 (14.1–14.7) mm (Allen 1917a, Hill 1969).

Myotis daubentonii

Similar Species Four other African molossids have ears without complex folds:

Myotis whiteleyi. Much smaller (FA: 35–37 mm; GLS: 16.6–18.5 mm). Dorsal pelage without lateral bands.

Mormopterus spp. Much smaller (FA: 38–43 mm; GLS: 14.1–15.7 mm). Dorsal pelage without lateral bands. Wings dark brown. M³ with third ridge \geq second ridge.

Sauromys petrophilus. Dorsal pelage uniformly dark brown. Wings blackish-brown, brown or semi-translucent greyish-brown. M³ with third ridge present. South of 15° S.

Platymops setiger. Much smaller (FA: 27–36 mm; GLS: 14.7–17.0 mm). Dorsal pelage uniformly coloured.

Distribution Endemic to Africa. Mainly found in the Guinea Savanna BZ and the Northern Rainforest–Savanna Mosaic, but extending into the Sudan Savanna BZ in Senegal. Known from only eight localities in Senegal, Côte d'Ivoire, Central African Republic and DR Congo (Lang & Chapin 1917b, Hayman *et al.* 1966, Adam *et al.* 1993, J. Fahr unpubl.).

Habitat Predominantly a savanna species recorded in the following vegetation zones: Sudanian undifferentiated woodland savanna in Senegal, *Isobrerlinia* woodland (e.g. N'Délé in Central African Republic) and Rainforest–Savanna Mosaic (e.g. Lamto and Comoé N. P. in Côte d'Ivoire). Also recorded at 1250 m in montane grassland (Bunia, DR Congo). Specimens from Lamto were found roosting in a palm in grassland ca. 100 m from gallery forest (Brosset & Vuattoux 1968).

Abundance Uncertain. Only 23 specimens known. Apparently quite localized and rare.

Adaptations Most of the known specimens were taken in their day-roosts in hollow trees. These include the hollow trunk of a dead Palmyra Palm *Borassus aethiopum* in which the bats roosted at a height of ca. 12 m (Brosset & Vuattoux 1968). According to Freeman (1981), species of *Myotis* are characterized by broad wing-tips. She concluded that these species are probably more manoeuvrable than most other molossids and possibly fly more slowly. In contrast, preliminary flight-cage experiments indicate that *M. daubentonii* is less manoeuvrable than 16 other species of molossids tested (J. Fahr unpubl.). Individuals from Comoé N. P., Côte d'Ivoire, had a strong, spicy and almost pungent smell.

Foraging and Food Foraging strategy: fast-hawking. In Comoé N. P., in mist-nets set 0–25 m above ground, one ♂ and two ♀♀ were caught at the same time, at heights of 9, 14 and 20 m (J. Fahr unpubl.). Possibly these individuals were foraging together as group-foraging seems to be common in molossid bats. The mist-nets were set between two large trees in woodland savanna not far from gallery forest. The teeth and mandibles are very robust and powerful; from this, Freeman (1981) deduced that this bat is probably able to consume large and hard-shelled prey.

Social and Reproductive Behaviour Very little is known. One group in a hollow tree included a subadult ♂ and six ♀♀, but not all group-members were captured (Lang & Chapin 1917b). Another group included an adult ♂ and four adult ♀♀ (not stated if all group-members were captured) (Brosset & Vuattoux 1968), and a third group included three adult ♂♂, one subadult ♂ and one subadult ♀ (Adam *et al.* 1993).

Reproduction and Population Structure No information.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Data Deficient.

Distribution rather broad, but only eight localities known. Population trend inferred to be declining, in both past and future. Major threats: loss and degradation of habitat, particularly as result of logging and agriculture.

Myotis whitleyi **BINI WINGED-MOUSE BAT (WHITLEY'S WINGED-MOUSE BAT)**

Fr. Myoptère de Whitley; Ger. Bini Pergamentflügel-Fledermaus

Myotis whitleyi (Scharff, 1900). Ann. Mag. Nat. Hist., ser. 7, 6: 569. Benin City, Nigeria.

Taxonomy Originally *Mormopterus whitleyi*. Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 35–37 mm); head not flattened; ears well separated and without complex folds, whitish; upper lip smooth; wings partly white and partly transparent, contrasting with uniformly dark brown dorsal pelage. Sexes similar in colour, ♀♀ on average slightly larger than ♂♂. Pelage short (mid-dorsal hairs 4–5 mm). Dorsal pelage dark brown without stripes; hairs whitish with medium to dark brown at tip. Ventral pelage uniformly dirty-white, cream or pure white, in marked contrast to dorsal pelage; no mid-ventral markings; ventral flank-stripe white. Head not dorsoventrally flattened; muzzle smooth and rounded; almost naked except for dense patch of very stiff spoon-hairs on upper lip below nostrils, and fringe of stiff hairs along edge of upper lip; upper lip smooth. Ears erect (without complex folds), narrow and pointed, with apex unpigmented; bases of inner margins widely separated. Tragus large, squarish, not concealed by antitragus. No interaural crest. Gular gland in ♂♂. Wings with arm-wing membranes yellowish-white, hand-wing membranes transparent. Interfemoral membrane dorsally grey or pale brown, ventrally whitish. Skin on forearm, tibia and third finger dark pink.

Skull (Figure 107) low but not extremely dorsoventrally flattened. Sagittal crest absent or very indistinct except at the very back of the braincase where, in fully mature adults, it rises gradually or abruptly to form a small wing ca. 4 mm long. Lambdoid crest absent or weakly developed. Anterior palatal emargination closed. Basisphenoid pits deep. Upper incisors in contact. Anterior upper premolar absent. M³ with third ridge absent. Only one lower incisor on each side; bicuspid, not crowded. Lower canines with cingula not greatly enlarged, well separated. Dental formula: $\frac{1113}{1123} = 26$.

Geographic Variation None recorded, but data are limited.

Similar Species Four other African molossids have ears without complex folds:

Myotis daubentonii. Much larger (FA: 48–56 mm; GLS: 21.3–25.7 mm).

Dorsal pelage with contrasting lateral bands of paler colour.

Mormopterus spp. Forearm longer (38–43 mm); skull smaller (GLS: 14.1–15.7 mm). Wings and interfemoral membrane dark brown.

M³ with third ridge ≥ second ridge.

Sauromys petrophilus. Inner margins of ears meet to form V-shaped valley. Head extremely flattened. Wings blackish-brown, brown or semi-translucent greyish-brown. South of 15° S.

Platymops setiger. Head extremely flattened. Forearms with warty granulations. M³ with second and third ridges equal in length.

Distribution Endemic to Africa. Known only from the Rainforest BZ (Western, West Central, South Central and East Central Regions) and margins of the Eastern and Southern Rainforest–Savanna Mosaics. Known only from 20 localities in Ghana, Nigeria, Cameroon, Central African Republic, Gabon, DR Congo and Uganda (Hayman *et al.* 1966, Happold 1987, Adam *et al.* 1993, Van Cakenberghe *et al.* 1999, Barrière *et al.* 2002, J. Fahr unpubl.). Although based on rather few records, it seems that the distribution pattern is patchy or even disjunct. Conspicuously absent from central Congo Basin but its distribution in DR Congo is not confined to the Kasai River System as proposed by Hayman & Hill (1971) because it has also been found along the lower stretches of the Congo R. A record from Eala (Schouteden 1944, 1948, mentioned by Aellen [1952] as from

Myotis whitleyi

Coquilhatville) was based on a specimen (RMCA RG 5392) that Hayman *et al.* (1966) re-identified as *Tadarida pumila*.

Habitat Mainly recorded in rainforest–savanna mosaic, lowland rainforest and coastal forest vegetation zones, but also found in swamp forest and mangroves. Most of the localities are situated along the periphery of the Rainforest BZ. A single record from Kasenye near L. Albert, DR Congo, is from *Isoberlinia* woodland. Specimens from Calabar, Nigeria, were caught in a garden (ROM).

Abundance No information, but localized.

Remarks Day-roosts of *M. whitleyi* are variable and in some cases unusual for a molossid: specimens have been taken among the leaves of plantains, clinging to the outside of a *Cola* tree and in houses (Rosevear 1965). Surprisingly, a single, uninjured individual was captured on the ground in a bucket in a pitfall-trap line (Barrière *et al.* 2002).

Predators, Parasites and Diseases Ectoparasites include fleas *Lagarosylla obliqua*, *Allopsylla hetera* and *A. lobayensis* (Siphonaptera: Ischnopsyllidae) and a mite *Dentocarpus tenuis* (Acari: Chirodiscidae) (Beaucournu & Fain 1982, Anciaux de Faveaux 1984, Barrière *et al.* 2002).

Conservation IUCN Category: Least Concern.

GENUS *Otomops* Giant Mastiff Bats

Otomops Thomas, 1913. J. Bombay Nat. Hist. Soc., 22: 91. Type species: *Nyctinomus wroughtoni* Thomas, 1913.

Otomops martiensseni.

Otomops currently contains seven species of which only one occurs in Africa; the others occur in Madagascar, S India, Java, Lesser Sundas Is. or New Guinea (Simmons 2005). Distinguished from other genera of molossids in Africa by the following combination of characters: head, body and skull low but not extremely flattened dorsoventrally; ears uniquely shaped with only moderate folding, forward-projecting and joined to the long muzzle (Figure 97b); no tragus; no antitragus; dorsal hairs bicoloured; a band of pale or white pelage across shoulders and along each flank above the wings; upper lip with fine, microscopic wrinkles and no spoon-hairs; basisphenoid pits very deep; third ridge of posterior upper molar (M³) as long or almost as long as the second ridge; dental formula: $\frac{1123}{2123} = 30$ (see also Table 19, p. 472). Selected characters of *Otomops martiensseni* are illustrated in Figure 108.

Otomops martiensseni showing ear flap folded down (upper) and open (lower).

The genus was reviewed by Peterson *et al.* (1995). Based on non-metric multidimensional scaling, these authors recognized all previously named forms of *Otomops* as distinct species (with the exception of

Figure 108. African *Otomops*. Flight membranes, and bones of wing, hindlimb and tail of *O. martiensseni* (BMNH 1975-914).

O. johnstonei from Indonesia, which was not described until 1992 and not included in their study), but they considered *O. icarus* very similar to *O. martiensseni*, and were uncertain of its specific status. This form is now considered to be a subspecies of *O. martiensseni* (see species profile). Peterson *et al.* (1995) found *O. madagascariensis* from Madagascar to be morphologically quite different from the African

O. martiensseni, and more closely related to *O. formosus* from Java, Indonesia than to any other species.

The species found in Africa is *O. martiensseni*.

Meredith Happold

Otomops martiensseni LARGE-EARED GIANT MASTIFF BAT

Fr. Grand molosse oreillard; Ger. Großohrige Riesen-Bulldoggfledermaus

Otomops martiensseni (Matschie, 1897). Arch. Naturgesch. 63 (1): 84. Magrotto Plantation, near Tanga, SE Usambara Mts, Tanzania.

Taxonomy Originally *Nyctinomus martiensseni*. Synonyms: *icarus*. Subspecies: two. A Madagascan form, *madagascariensis*, is considered to be a distinct species by Peterson *et al.* (1995) and Goodman (2011) although often considered a subspecies of *O. martiensseni* (e.g. Harrison 1957a, Koopman 1993, 1994). Chromosome number (Kenya): $2n = 48$; $aFN = 56$ (Dulić & Mutere 1973b) or 58 (Warner *et al.* 1973).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; the largest African molossid (FA: 61–74 mm); ears very large, forward-projecting with inner margins joined together and to muzzle; dorsal pelage with band of pale pelage across shoulders and along flanks; dorsal hairs bicoloured. Sexes similar in colour; ♂♂ on average larger than ♀♀. Pelage soft, dense; mid-dorsal hairs 6–7 mm. Dorsal pelage dark brown with dark rusty-brown tinge, or blackish-brown, darker on head and body, with pale brown or white band across shoulders, and a thin band of pale brown separating the dark dorsal pelage from the dark wing-membrane on each side; mid-dorsal hairs dark brown with whitish base. Ventral pelage dark brown, throat paler. Head not flattened; face pink; snout ‘pig-like’. Upper lip expansible with many fine wrinkles, no spoon-hairs. Ears rounded, fairly stiff, projecting forward well beyond snout; inner margins joined together and to muzzle (Figure 97b). Tragus minute; antitragus absent. A semi-circular flap extends forward from base of ear;

can be folded down to seal auditory meatus. No interaural crest. Gular sac (gular gland) present in both sexes; well developed in adult ♂♂ (Harrison 1957b). Wings and interfemoral membrane blackish-brown.

Skull (Figure 108) not extremely dorsoventrally flattened. Anterior of braincase moderately elevated above plane of rostrum. Each zygomatic arch with a very prominent vertical projection. Sagittal crest moderate; lambdoid crest low or absent; no helmet. Anterior palatal emargination very narrow and deep. Basisphenoid pits very deep and much wider than the very narrow septum between them (as in Figure 101b). Dentition weak. Anterior upper premolar small but rising well above cingulum of posterior premolar. M^3 with third ridge equal or just a little shorter than second. Two lower incisors on each side, bicuspid, not crowded. Lower canines with cingula weakly developed (cf. *Tadarida*) and well separated. Dental formula: $^{1123}/_{2123} = 30$.

Similar Species None.

Geographic Variation Koopman (1994) lists two African subspecies:

O. m. icarus: Angola and Malawi to KwaZulu–Natal. Smaller (FA [KwaZulu–Natal]: 62–68 mm).

O. m. martiensseni: remainder of African geographic range. Larger (FA [Ethiopia]: 69–74 mm).

Otomops martiensseni

The validity of *icarus* as a subspecies, and its distribution, have been questioned (Hill & Carter 1941, Meester *et al.* 1986). The possibilities of a clinal decrease in size with increasing latitude within one species, or the existence of two distinct species, need investigation. See also Lamb *et al.* (2006, 2008) and Monadjem *et al.* (2010).

Distribution In Africa, widely but apparently disjunctly distributed in the Somalia–Masai Bushland, Coastal Forest Mosaic, Zambezan Woodland and Afromontane–Afroalpine BZs in the eastern side of Africa from Djibouti to KwaZulu–Natal, South Africa. Also three isolated records in the Guinea Savanna BZ (Côte d’Ivoire, Ghana, Central African Republic), one record from the Rainforest BZ (DR Congo), and one isolated record from the Zambezan Woodland BZ (Angola). This bat is difficult to catch (except at day-roosts), therefore the disjunctions probably reflect insufficient sampling. Extraliminally: Yemen.

Habitat Found in a wide range of habitats, from semi-arid scrub to montane forests, from urban and agricultural areas to undisturbed areas, and from sea level to 2000 m.

Abundance Uncertain. Seldom recorded throughout most of geographic range, but two colonies numbering >300 and several thousand were reported in 1960s by Mutere (1973b). Kock *et al.* (2005) provides further evidence that the two breeding colonies in Kenya may fluctuate in numbers (possibly due to migration) but can number tens of thousands. Common in certain residential suburbs in and around Durban, KwaZulu–Natal (Fenton *et al.* 2002).

Adaptations Aspect ratio very high; wing-loading high to very high; wing-tips broad; flight fast (9.5 m/sec for bat flying 20 m above ground); agile with poor manoeuvrability; uses side-slips to decrease altitude rapidly (Norberg 1976, Norberg & Rayner 1987, Rydell & Yalden 1997, Fenton *et al.* 2002). During flight, the somewhat rigid

ears project forward; the flap behind the antitragus can either open or close the auditory meatus – Kingdon (1974) suggests that the flap closes to increase streamlining; Valdivieso *et al.* (1979) suggest that it closes to protect the ear from intense noises. In Kenya, roosts by day on ceilings of caves including lava tunnels, preferring darker, poorly ventilated positions (Mutere 1973b). Becomes torpid during day (Mutere 1973b, D. W. Yalden pers. obs.). Emerges well after dark. Sometimes shares caves with *Rhinolophus* sp., *Miniopterus* sp. and *Triaenops afer*. In KwaZulu–Natal, roosts by day under roofs of houses and apartments in built-up areas, preferring old 2–3 storey houses, some of which have been occupied by bats for at least nine years (Taylor, P. 1998, Fenton *et al.* 2002). Entrances are high to allow diving to gain sufficient speed for flight, and so small that the bats have to scuttle in and out of them. Individuals hang or cling, face downwards, with their bellies in contact with vertical surfaces, or cling to horizontal surfaces. They huddle together and do not appear to become torpid during the day. Radio-tracking revealed that ♂♂ and also ♀♀ in different reproductive conditions used at least two day-roosts and up to four different day-roosts over a 12-day period (Fenton *et al.* 2002). Bats begin to emerge 15–30 min after sunset. *Otomops martiensseni* is docile to handle and, despite its pugnacious appearance, makes no attempt to bite handlers. For further adaptations, see Long (1995).

Foraging and Food Forages by fast-hawking in open spaces, probably at fairly high altitudes (see below). Because food resources near caves sheltering thousands of individuals are likely to be limited, these bats presumably travel long distances from their day-roosts while foraging. Local fluctuations in populations suggest that some individuals migrate seasonally at times of food-shortage (Mutere 1973b), but this needs confirmation. Radio-tracked bats in the Durban area, South Africa, covered considerable distances while foraging; most bats foraged more than 3 km from their day-roosts for most of the night; one ♂ night-roosted 6.8 km from his day-roost, and two ♀♀ night-roosted at least 10 km away (Fenton *et al.* 2002). Analysis of faecal pellets from Kenya and Rwanda indicated that moths comprise 97–100% by volume of the diet (Rydell & Yalden 1997) and, as in other molossid moth-specialists, the jaws are slender and the dentition weak (Freeman 1981).

Echolocation Search-phase call-shapes (South Africa): (a) very shallow linear or quasi-linear FM; start-frequency ca. 18 kHz; end-frequency ca. 9 kHz; peak-frequency 10–12 kHz; call-duration 5–50 ms; maximum energy in fundamental harmonic, other harmonics uncommon; and (b) lilt calls – as above but end with a shallow upward sweep (lilt), and include the second harmonic (Fenton *et al.* 2002). Lilt calls are most common in calls lasting over 25 ms. In cluttered surroundings (e.g. when emerging from day-roosts) individuals emit pairs of multiharmonic calls (7–16 kHz, peak-frequency 11 kHz), which are audible to humans (Taylor 2000). No feeding-buzzes were heard during more than 20 h of monitoring. Calls with frequencies 10–13 kHz, recorded 500–550 m above ground, were assumed to have been emitted by *O. martiensseni* by Fenton & Griffin (1997) because they resembled the low frequency calls of a light-tagged individual (Fenton & Bell 1981). These audible calls are lower in frequency than those detected by species of moths that can hear ca. 20–40 kHz and dive to avoid capture by bats echolocating at these frequencies.

Social and Reproductive Behaviour In Kenya, *O. m. martiensseni* roosts in very large groups (colonies) of several hundred to several thousand individuals of both sexes; social organization not known. In KwaZulu–Natal, *O. m. icarus* roosts singly, or in groups of up to 29 individuals that are typically comprised of one adult ♂, several adult ♀♀ and young: this suggests a harem mating system (Taylor, P. 1998, Fenton *et al.* 2002). Discounting four records of single bats, and two records of only two bats, 24 colonies averaged 11.2 ± 6.7 individuals (mean \pm S.D.). Males with well-developed gular sacs (gular glands) were found with ♀♀ and young outside the mating season, suggesting that the harem associations are not just related to mating, and year-round maintenance of harems is suggested by Fenton *et al.* (2004). Radio-tagged bats from different colonies were never observed roosting in the same houses. Roosting group-members usually hang in physical contact with each other, and make social vocalizations, which are audible to humans. Group-members emerge from a roost singly, at 3–10 min intervals, but remain in the vicinity and emit FM sweeps that have individual signatures permitting individuals to be recognized; these seem to have a communication function and perhaps are not used in echolocation (Fenton *et al.* 2004). This behaviour continues for ca. 5–30 min, apparently until other bats from the roost join those calling in flight. Because, on any one day, group-members are sometimes in different buildings, their signature-calls perhaps play an important role in synchronizing group activities away from the roosts (Fenton *et al.* 2004).

Reproduction and Population Structure Litter-size: one. Left ovary non-functional; implantation always in right horn. At 1–3°S (Ithundu and Mt Suswa, inland Kenya), the reproductive chronology is mainly restricted seasonal monoestry with 86% of 153 ♀♀ pregnant in Nov and most births at beginning of wet season (Nov–Dec) (Mutere 1973b). Gestation suggested to be ca. three months. A few pregnant ♀♀ were recorded in Jan (4%), Feb (1%) and May (2%) but no evidence of polyoestry was recorded. Testes size maximum in Aug, low Dec–May; gular sac of ♂♂ shows similar cycle. Neonates naked and pink; seldom cling to their mothers; form clusters often apparently surrounded by their mothers. Sex ratio of juveniles usually 1 : 1, but the ratio of ♂♂ : ♀♀ in adults apparently varies from 1 : 2 to 3 : 1 in different sites and years.

At 29–30°S (KwaZulu–Natal, South Africa) the chronology appears to be extended seasonal monoestry, with juveniles recorded Oct–Jan and in May and Jun; but data are limited and it is not yet known if some ♀♀ are polyoestrous (Taylor, P. 1998, Fenton *et al.* 2002). The ratio of adult ♂♂ : ♀♀ in colonies was skewed towards ♀♀ and, in five colonies, ranged from 1 : 2 to 1 : 11 (Fenton *et al.* 2002). The sex ratios at birth and in the adult population as a whole are not known.

Predators, Parasites and Diseases Ectoparasites include a flea *Araeopsylla scitula* (Siphonaptera: Ischnopsyllidae); a tick *Carios boueti* (Acari: Argasidae); and mites *Chiroptella suswaensis* (Acari: Trombiculidae), *Olavidocarpus otomops*, *Labidocarpellus abyssinicus* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984, Beaucornu & Kock 1996). Bat fleas parasitizing *O. martiensseni* increase to tremendous numbers at certain periods of the year; e.g. 662 *A. scitula* on one juvenile (Beaucornu & Kock 1996).

Conservation IUCN Category: Near Threatened.

Guano collection from one breeding-cave was thought to be the cause of variation in apparent reproductive success there from year to year (Mutere 1973b). This thinly distributed and highly colonial species would be very vulnerable to disturbance of this sort. In and around Durban, South Africa, where *O. martiensseni* roosts in houses and is one of the most commonly encountered bats, the bats themselves, and the amateur and professional people studying them, have received wide positive local publicity and this has made many of the human residents of the area more interested in the bats and more tolerant of them as co-inhabitants (Fenton *et al.* 2002). In this area, *O. martiensseni* is clearly able to find and exploit roosts in urban areas and thrive in areas of intensive agricultural operations, and could have a role as a flagship species representing the resilience of nature (Fenton *et al.* 2002).

D. W. Yalden & Meredith Happold

GENUS *Platymops* Peters's Flat-headed Bat

Platymops Thomas, 1906. Ann. Mag. Nat. Hist., ser. 7, 17: 499. Type species: *Platymops macmillani* Thomas, 1906 (= *Platymops setiger* Peters, 1878).

Platymops is a monotypic genus known only from S Sudan, Ethiopia and Kenya. Distinguished from other genera of molossids in Africa by the following combination of characters: head and body extremely flattened (as in *Sauromys*); ears widely separated and without complex folding; wart-like granulations on FA (unlike all other African genera); gular sac (gular gland) well developed; upper lip with many fine wrinkles and many stiff bristles; dental formula probably $^{1123}/_{2123} = 30$ but with some variations (see species profile; see also Table 19, p. 472). Selected characters of *Platymops setiger* are illustrated in Figure 109. *Platymops* was elevated to generic status (distinct from *Mormopterus*) by Thomas (1906c), but subsequently considered a subgenus of *Mormopterus* by some authors including Freeman (1981), Legendre (1984) and Koopman (1993, 1994). Considered here as distinct following Harrison & Fleetwood 1960, Peterson (1965, 1985), Meester *et al.* (1986), Peterson *et al.* (1995) and Simmons (2005).

The only species currently recognized is *P. setiger*.

Meredith Happold *Platymops setiger*.

Figure 109. *Platymops setiger*. Flight membranes (traced from photo of dried skin in Harrison & Fleetwood 1960), and bones of wing and hindlimbs. Skull (HZM 6.3776): the anterior premolar is missing in this specimen.

Platymops setiger PETERS'S FLAT-HEADED BAT

Fr. Molosse à tête plate de Peters; Ger. Peters' Flachkopf-Bulldoggfledermaus

Platymops setiger (Peters, 1878). Monatsber. K. Preuss. Akad. Wiss. Berlin 1878: 196. Taita, Kenya.

Taxonomy Originally *Mormopterus setiger* but see Genus *Platymops*. Synonyms: *barbatogularis*, *macmillani*, *parkeri*. Subspecies: none currently recognized. Reviewed by Peterson (1965). Chromosome number (Kenya): $2n = 48$; $aFN = 54$ (Warner *et al.* 1974).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid; head and body extremely flattened; ears well separated and without complex folds; upper lip without well-developed wrinkles; dorsal pelage without stripes; wart-like granulations on forearms and elsewhere; anterior

upper premolar minute or absent. Sexes similar. Pelage short (mid-dorsal hairs 3–4 mm). Dorsal pelage pale sepia brown, rusty-brown, brownish-grey or blackish; hairs with basal half dark cream. Ventral pelage rusty-yellow or creamy-white; sometimes with a darker to much darker lateral stripe beginning on neck and extending a variable distance along each flank, with a narrow band of brownish, rusty-yellow or creamy-white pelage between the lateral stripe and the wing-membrane. Head flattened dorsoventrally. Upper lip thick, relatively rigid, with many very fine microscopic wrinkles (giving lip a skirt-like appearance), and many dense, stiff bristles. Ears dark brown, well separated, without complex folds (cf. *Tadarida*). No interaural crest. Both sexes with small gular sac (gular gland) containing tuft of coarse, brownish hairs in the form *barbatogularis*, untufted in other forms (details in Harrison & Fleetwood 1960). Wings long, narrow, semi-translucent, lightly pigmented with dark brown, especially over bones; wart-like granulations on forearm, thumb and third metacarpal, and also on tail. Toes with long bristles (up to 8 mm).

Skull (Figure 109) extremely dorsoventrally flattened (maximum height 28–34% of GLS). Anterior of braincase not elevated above plane of rostrum. Sagittal crest low or absent anteriorly, moderate or absent posteriorly; lambdoid crests moderate to well developed (especially in adult ♂♂). Lachrymal ridges well developed and forming a prominent tubercle on each side of rostrum (cf. *Mormopterus* and *Sauromys*). Anterior palatal emargination narrow. No basisphenoid pits. Upper incisors bicuspid, well separated; tall, curved, deciduous milk incisors may be retained in immature specimens. Anterior upper premolar absent in adults but sometimes there is a minute spicule (probably a deciduous milk tooth) in younger animals, displaced labially; canine and posterior premolar in contact or almost so. M^3 with second and third ridges equal in length. Usually two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged and not in contact. Dental formula: probably $1^{123}/_{2123} = 30$ (but see above).

Geographic Variation Uncertain. Peterson (1965) recognized two subspecies on the basis of size: *P. s. setiger* in S Kenya, and a smaller form, *P. s. macmillani*, in the remaining geographic range. However, Peterson's samples were very small (eight adult *setiger*, 11 adult *macmillani*). Furthermore, as the distribution of this species is apparently contiguous, the variation is possibly clinal. In *barbatogularis* from Sudan (described as a species but now considered a synonym of *macmillani* by Simmons 2005), the gular sac contains a prominent tuft of brownish hairs (cf. *macmillani*) (Harrison 1956).

Similar Species Four other African molossids have ears without complex folds:

Sauromys petrophilus. Ears meeting to form V-shaped valley. Forearms without warty granulations. Upper lip smooth. No gular gland. Skull with lachrymal ridges indistinct. Anterior upper premolar present and about same height as cingulum of posterior premolar; canine and posterior premolar well separated.

Mormopterus spp. Head not extremely flattened. Forearms without warty granulations. Skull without very prominent lachrymal ridges.

Myopterus daubentonii. Much larger (FA: 48–56 mm; GLS: 21.3–25.7 mm). Dorsal pelage usually with contrasting lateral bands of paler colour.

Platymops setiger

Myopterus whitleyi. Head not extremely flattened. Forearms without warty granulations. M^3 with third ridge absent.

Distribution Endemic to Africa. Apparently confined to a narrow belt through the Somalia–Masai Bushland BZ (and marginally into the Sudan Savanna BZ) from SE Sudan and SW Ethiopia to SE Kenya (Largen *et al.* 1974, Koopman 1975, Aggundey & Schlitter 1984). Not known to extend into the Horn of Africa (*contra* Kingdon 1974).

Habitat At Masalani, near Kibwezi in inland Kenya, recorded from dense thorn scrub (*Combretum*, *Grewia*, *Premna*) with scattered patches of grassland (O'Shea & Vaughan 1980). Elsewhere, recorded from dry stony areas, and areas with rocky hills, in Ethiopian undifferentiated woodland, Somalia–Masai *Acacia–Commiphora* bushland and thicket, and mosaics of East African evergreen bushland and secondary *Acacia* wooded grassland (terminology: White 1983).

Abundance Uncertain.

Adaptations Wings short for an African molossid; metacarpal of third finger only ca. one-third longer than metacarpal of fifth finger (Thomas 1906c). Flight described as fast, direct or erratic. Roosts by day in very narrow crevices under stones or rocks lying on the ground, and in fissures in granite hills: sometimes found cohabiting with scorpions (Harrison & Fleetwood 1960). Able to squeeze into these confined spaces because head and body are flattened. Tactile hairs on feet and muzzle (as in other molossids) also facilitate movement into the day-roosts. According to Kingdon (1974), the tip of the tail is held aloft to gauge heights of crevasses, and the ears and raised phalanges of third and fourth fingers are also used for this purpose. Roosts have strong smell. Emergence is at dusk (Williams 1967).

Foraging and Food Forages by fast-hawking (O'Shea & Vaughan 1980). Has been observed flying over waterholes and marshes, at

heights of 9 m and less (Nowak 1999). Small beetles recorded in diet.

Social and Reproductive Behaviour Recorded roosting singly and in groups of up to five (Nowak 1999). No other information.

Reproduction and Population Structure Litter-size: one ($n = 4$; Anciaux de Faveaux 1972, O'Shea & Vaughan 1980). Reproductive chronology not known.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

GENUS *Sauromys* Roberts's Flat-headed Bat

Sauromys Roberts, 1917. Ann. Transvaal Mus., 6: 5. Type species: *Platymops petrophilus* Roberts, 1917.

Sauromys is a monotypic genus almost certainly found only in southern Africa. Simmons (2005) lists Ghana as a possible locality, and Meester *et al.* (1986) refer to an immature specimen from that country in the USNM collection. However, D. E. Wilson (pers. comm. in Jacobs & Fenton 2001) found that the USNM collection contained no specimens other than 38, all of which came from southern Africa. No records from Ghana are reported by Grubb *et al.* (1998). *Sauromys* is distinguished from other genera of molossids in Africa by the following combination

of characters: head, body and skull extremely flattened (as in *Platymops*); ears without complex folding and with inner margins separated by narrow gap (cf. ears widely separated in *Platymops*); no wart-like granulations on forearm; no gular sac (gular gland); upper lip smooth with few coarse bristles; third ridge of posterior upper molar (M³) equal in length to second ridge; dental formula: $^{1123}/_{2123} = 30$. The flight membranes, and bones of wing, hindlimb and tail, and the lateral, dorsal and ventral views of the skull are illustrated in Figure 110.

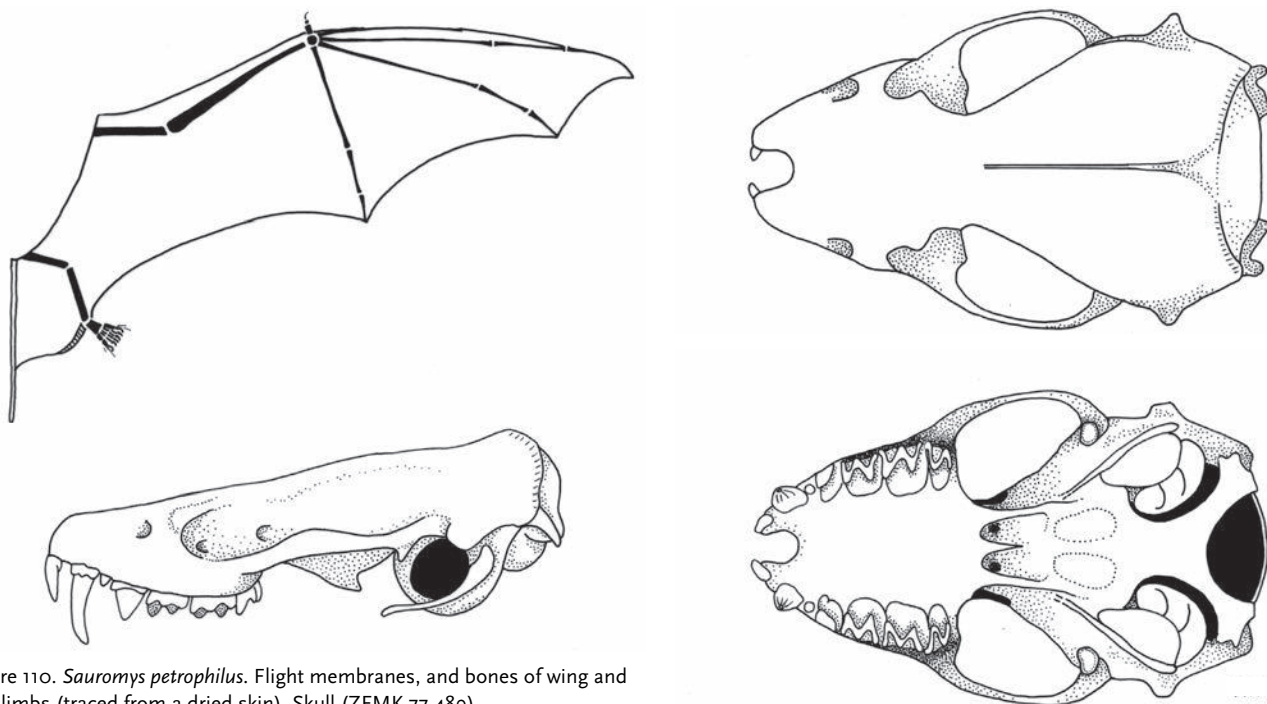

Figure 110. *Sauromys petrophilus*. Flight membranes, and bones of wing and hindlimbs (traced from a dried skin). Skull (ZFMK 77.489).

Sauromys was described as a subgenus of *Platymops*, then raised to generic status by Peterson (1965). Subsequently, it has been considered a subgenus of *Mormopterus* by Freeman (1981) and others including Legendre (1984) and Koopman (1993, 1994). It is considered a distinct genus here, following Peterson (1965), Meester

et al. (1986), Corbet & Hill (1992), Peterson *et al.* (1995) and Simmons (2005).

The only species is *S. petrophilus*.

Meredith Happold

Sauromys petrophilus ROBERTS'S FLAT-HEADED BAT

Fr. Molosse à tête plate de Roberts; Ger. Roberts Flachkopf-Bulldogfledermaus

Sauromys petrophilus (Roberts, 1917). Ann. Transvaal. Mus. 6: 4. Bleskop, near Rustenburg, Northwest Province, South Africa.

Taxonomy Originally *Platymops* (*Sauromys*) *petrophilus*. Synonyms: *erongensis*, *fitzsimonsi*, *haagneri*, *umbratus*. Subspecies: five of uncertain validity. Chromosome number (Namibia, South Africa): $2n = 48$; $aFN = 62$. X = medium-sized submetacentric; Y = small acrocentric (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-small for an African molossid; head and body extremely flattened; ears separated and without complex folds; dorsal pelage without stripes; forearms without wart-like granulations; anterior upper premolar well developed. Sexes similar in colour; ♀♀ on average slightly larger than ♂♂. Pelage soft and dense; mid-dorsal hairs 5–6 mm. Dorsal pelage dark brown, medium yellowish-brown, greyish-brown, dark grey to pale grey; hairs brown with the various shades of brown or grey at tip. Ventral pelage fairly dark greyish-brown, pale grey to whitish; flanks sometimes darker than throat and abdomen; chin naked. Head extremely dorsoventrally flattened. Upper lip smooth and with comparatively few coarse bristles (not spoon-hairs). Ears moderately large but not extending beyond muzzle when laid forward, broad, without complex folds; inner margins separated by narrow gap (Figure 97e) (cf. *Tadarida pumila* with which it has been confused [Jacobs & Fenton 2002]). Antitragus indistinct. Tragus very small. No interaural crest. No gular gland. Wings long, narrow, blackish-brown, brown to semi-translucent greyish-brown.

Skull (Figure 110) extremely dorsoventrally flattened (maximum height 32 [24–37]% of GLS, $n = 22$). Zygomatic arches slender. Anterior of braincase not elevated above plane of rostrum. Sagittal crest indistinct and depressed in shallow parietal groove; lambdoid crest moderate. Lachrymal ridges indistinct and forming a comparatively small tubercle on each side of rostrum (cf. *Platymops setiger*). Anterior palatal emargination wide; upper incisors well separated. Basisphenoid pits shallow (indistinct), large, their width much greater than their distance apart. Upper incisors with small secondary cusp on lateral side, just below gum. Anterior upper premolar about same height as cingulum of posterior premolar, within tooththrow; canine and posterior premolar well separated (Figure 103c). M^3 with second and third ridges equal in length. Two lower incisors on each side. Lower canines with cingula not greatly enlarged and not in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Five subspecies (which were provisionally retained by Peterson 1965) are recognized by Koopman (1994) and Simmons (2005): *S. p. petrophilus*, *S. p. erongensis*, *S. p. fitzsimonsi*, *S. p. haagneri*, *S. p. umbratus*. However, they are based on colour differences

and their validity is uncertain (Smithers 1983, Meester *et al.* 1986). No subspecies are recognized by Jacobs & Fenton (2002).

Similar Species Four other African molossids have ears without complex folds:

Platymops setiger. Ears well separated. Forearm with warty granulations. Upper lip with many wrinkles. Gular sac (gland) present, albeit small, in both sexes. Skull with lachrymal ridges very well developed and prominent. Anterior upper premolar absent (but sometimes a minute spicule, probably a milk tooth, is present in younger animals); canine and posterior premolar in contact or almost so.

Mormopterus spp. Inner margins of ears widely separated in *M. acetabulosus* (but almost touching and joined by a slender band of skin in *M. francoismoutoui*). Head not extremely flattened. Anterior upper premolar absent.

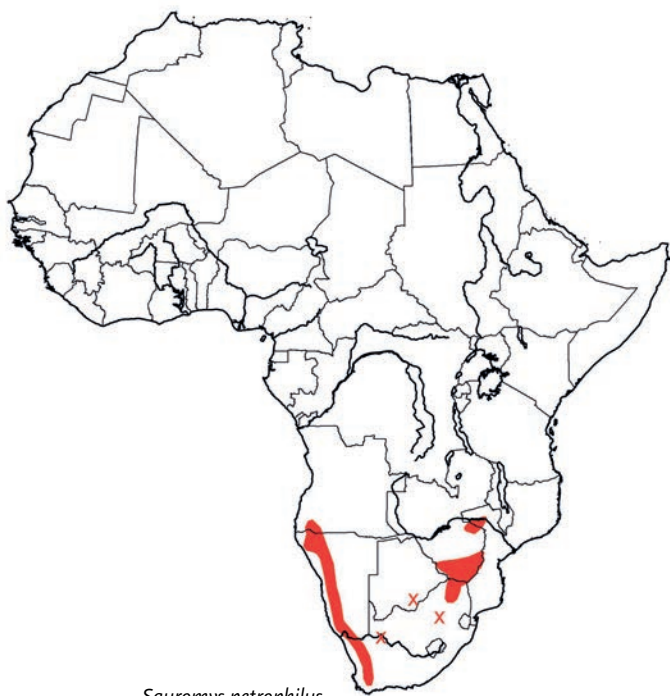

Myopterus daubentonii. Dorsal pelage usually with contrasting lateral bands of paler colour. Wings with arm-wing white, hand-wing transparent. M^3 with third ridge absent. North of Equator.

M. whiteleyi. Inner margins of ears widely separated. Head not extremely flattened. Arm-wing yellowish-white; hand-wing transparent. North of 10° S.

Distribution Endemic to Africa. Found in the Zambezi Woodland BZ south of Zambezi R., the South-West Arid BZ and the South-West Cape BZ. Recorded marginally in SW Angola (Crawford-Cabral 1986), and in Botswana, Zimbabwe, W Mozambique and South Africa (Smithers 1983). In Zimbabwe, widespread across the S, E and NE regions below 1300 m, but inexplicably absent from large areas of semi-arid savanna woodland in N and W Zimbabwe where suitable day-roosts in granitic and Karoo sandstone outcrops appear abundant (F. P. D. Cotterill unpubl.). Meester *et al.* (1986) reported an immature specimen from Ghana (USNM) tentatively assigned to *S. petrophilus*, but subsequently this could not be traced (Jacobs & Fenton 2002). Specimens from Cederberg in South-West Cape BZ listed as *Tadarida pumila* by Meester *et al.* (1986) have been re-identified as *S. petrophilus* (Jacobs & Fenton 2001).

Habitat Wetter and drier woodland savannas (including miombo, mopane and undifferentiated woodlands), shrublands, *Acacia*-wooded grasslands and deserts; always in areas with rocky outcrops and hills, principally of Karoo sandstones and granitic intrusions.

Abundance Locally abundant in areas where roosts are abundant, notably Mutoko district (NE Zimbabwe), Matobo Hills, Limpopo

*Sauromys petrophilus*

valley (SW Zimbabwe) and Cederberg (South-West Cape, South Africa). Elsewhere scarce.

Adaptations Aspect ratio high; wing-loading medium (Jacobs & Fenton 2002). Based on wing morphology, predicted to fly fast with poor manoeuvrability. Scuttles and climbs very efficiently. By day, roosts under slabs of exfoliated granite or sandstone, and in narrow fissures; roosts located near ground level in precipices. One roost was shared with 18 lizards *Platysaurus* sp. (Rautenbach 1982). The extreme flattening of the head, and the ability to fold-down the ears, enables *S. petrophilus* to squeeze into very narrow cracks and crevices. In Namibia, captive bats did not need to drink regularly (Roer 1970).

Foraging and Food Based on wing morphology, predicted to forage by fast-hawking. Reported flying as high as 37 m (Irwin & O'Donnelly 1962 in Freeman 1981). Most often captured over open water (Jacobs & Fenton 2002), but possibly because individuals come down to drink. Based on craniodental morphology, Freeman (1981) predicted that this species would feed mainly on small, soft-bodied insects, but the stomachs of 11 individuals contained both moths, beetles and other insects (Freeman 1981). Analysis of faecal pellets

from 14 individuals indicated that the diet was predominantly hard-shelled insects: Coleoptera (43%), Hemiptera (29%), Hymenoptera (18%). Soft-bodied prey (Lepidoptera, Diptera and Neuroptera) comprised ca. 10% of the diet (Jacobs & Fenton 2002).

Echolocation Search-phase call-shape: shallow FM (no details available). Start-frequency 31.4–43.5 kHz; end-frequency 26.7–30.9 kHz; bandwidth 3.9–14.7 kHz; call-duration 5.0–10.2 ms; peak-frequency 28.0–37.5 kHz (eight bats, 30 calls; Jacobs & Fenton 2002).

Social and Reproductive Behaviour Mostly found roosting singly, in pairs or in groups of up to four (Smithers 1971, 1983). Group-members huddle closely together, but scatter if disturbed.

Reproduction and Population Structure No conclusive information. In NE Zimbabwe, pregnant and lactating ♀♀ have been mist-netted in mid-Nov; ♀♀ examined during cool-dry season were neither visibly pregnant nor lactating.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

GENUS *Tadarida*

Tadarine Free-tailed Bats

Tadarida Rafinesque, 1814. *Precis. Som.*, p. 55. Type species: *Cephalotes teniotis* Rafinesque, 1814.

Tadarida (*sensu lato*) contains 43 species (Simmons 2005), of which ca. 27 species occur in Africa; the remainder are found in Madagascar, Mauritius, Aldabra, São Tomé, Príncipe, S Europe, India to Japan, Malay Archipelago to Philippines, Australia, some Pacific islands and the New World. Some African species recognized as distinct by

Simmons (2005) are considered here to have subspecific status, and some species listed by Simmons (2005), and profiled here, probably contain more than one species. Since this profile was submitted, a new species has been described (as *Mops* [*Xiphonycteris*] *bakarii*) by Stanley (2008) (see *Tadarida brachyptera* for more information). This species is

not included in tables and maps. African *Tadarida* are distinguished from other genera of molossids in Africa by the following combination of characters: head, body and skull not extremely flattened although low in some species; ears complexly folded, never whitish or translucent, inner margins meeting (or almost meeting) to form V-shaped valley or joined by band of skin (never widely separated or separated by a narrow gap); upper lip thick, usually with prominent vertical wrinkles and many spoon-hairs; forearms never with warty granulations; dental formula: $^{1113}/_{2123} = 28$, $^{1123}/_{2123} = 30$, or $^{1123}/_{3123} = 32$. The length of the third ridge of posterior M^3 relative to the second ridge is highly variable within *Tadarida*.

Of the 28 species found in Africa, one is a Palearctic species found in North Africa, five are found mainly in forests, 11 mainly in savannas, seven in both forest and savanna habitats, three in savanna and arid habitats, and one only on Mafia I. Five species, *T. brachyptera*, *T. condylura*,

T. nigeriae, *T. pumila* and *T. thersites* often roost under the corrugated iron roofs of houses occupied by humans, and may well have become more abundant as a result of this adaptation. Although sometimes noisy and smelly, they probably play an important role in controlling insects including some that damage crops.

The taxonomy and systematics of *Tadarida* is controversial. Many authors, mainly following Freeman (1981), consider the forms *Chaerephon* and *Mops* to be distinct genera, and *Xiphonycteris* a subgenus of *Mops* (e.g. Koopman 1993, 1994, Simmons 2005). Many others, including Legendre (1984), Meester *et al.* (1986), Corbet & Hill (1992) and Peterson *et al.* (1995) recognize these forms as subgenera of *Tadarida*. It is currently considered probable that *Chaerephon*, *Mops* and *Tadarida* (*sensu stricto*) are not monophyletic. Furthermore, the affinities of some species are unclear and their placement in these taxa depends on what diagnostic characters are

Table 20. Key to the African species in the genus *Tadarida* (*sensu lato*). The traditional subgenera to which the species have been allocated are given, but the monophyly of these taxa, and their taxonomic status is uncertain. Ventral flank-stripe in contrasting colour = band of ventral pelage adjacent to wing membrane (sometimes extending onto wing) the colour of which contrasts with that of the flanks adjacent to the flank-stripe. Ears can be small (extending about half-way along muzzle when laid forward) or large (extending well beyond snout when laid forward). Plantar pad = raised pad on sole of foot. Depth of basisphenoid pits in *Tadarida* may be shallow, moderate or deep, and the relative size of the pits (i.e. width relative to width of septum between pits) may be small (pit noticeably narrower than septum), medium (pit about as wide as septum) or large (pit noticeably wider than septum). For additional characters, see similar species listed in species profiles.

| Inner margins of ears | Upper M^3 : size of ridge 3 in relation to ridge 2 | Number of lower incisors on each side | Anterior palatal emargination | Ventral flank-stripe in contrasting colour (colour) | |
|---|--|---------------------------------------|-------------------------------|---|--|

| Meeting to form V-shaped valley. | $3 = 2$ | 3 | Wide | Absent | |
| Meeting to form V-shaped valley | $3 > \text{half } 2$ | 2 | Wide | Present (White) | |
| Meeting to form V-shaped valley | $3 > \text{half } 2$ | 2 | Wide | Present (White, cream or yellowish) | |
| Meeting to form V-shaped valley | $3 > \text{half } 2$ | 2 | Wide | Absent | |
| Separated by a large bulbous lobe projecting well over the forehead | $3 > \text{half } 2$ | 2 | Closed | Absent | |
| Separated by a flat lappet over a small, backward-opening pocket | $3 \geq \text{half } 2$ | 2 | Closed in adults | Present (White or whitish) | |
| Joined by band | $3 > \text{half } 2$ | 2 | Narrow | Present (Whitish) | |
| Joined by band | $3 > \text{half } 2$ | 2 | Narrow | Absent | |
| Joined by band | $3 > \text{half } 2$ | 2 | Narrow | Absent | |
| Joined by band | $3 > \text{half } 2$ | 1 or 2 | Closed or narrow | Present or absent (White or whitish) | |
| Joined by band | $3 > \text{half } 2$ | 1 or 2 | Closed or narrow | Present or absent (White or whitish) | |

given precedence. Pending revision and redefining of these taxa, we present all of the African species as members of *Tadarida* but give their traditional 'subgeneric' affinities in each profile. African members of the 'subgenera', as traditionally defined, can usually be distinguished by the following combinations of characters:

subgenus *Tadarida*: inner margins of ears meeting or almost meeting to form a V-shaped valley; third ridge of posterior upper molar (M^3) more than half length of second or equal in length; anterior palatal emargination wide.

subgenus *Chaerephon*: inner margins of ears joined by band of skin (except in *T. (C.) gallagheri* and *T. (C.) major*); third ridge of posterior upper molar (M^3) more than half length of second or equal in length; anterior palatal emargination closed (except *T. (C.) ansorgei*, *T. (C.) bemmeleni* and *T. (C.) bivittata* in which it is narrow).

subgenus *Mops*: inner margins of ears joined by band of skin (except perhaps *T. (M.) niangarae*); third ridge of posterior upper molar (M^3) less than half length of second or absent (except sometimes equal in *T. (M.) condylura*); anterior palatal emargination closed.

subgenus *Xiphonycteris*: inner margins of ears joined by band of skin; third ridge of posterior upper molar (M^3) less than half length of second or absent; anterior palatal emargination narrow.

The African species of *Tadarida* (*sensu lato*) can be distinguished by the combination of characters in Table 20, but additional information under Similar Species in all profiles should be consulted in conjunction with this table-key. Many African molossids are very difficult to distinguish, and it is important to use cranial and dental characters as well as external characters. Many of the relevant diagnostic characters are illustrated in the profile of the family Molossidae.

In the text, the species of *Tadarida* (*sensu lato*) are presented in alphabetical order irrespective of the traditional subgenera to which they have been allocated by some authors.

***Tadarida aegyptiaca* EGYPTIAN FREE-TAILED BAT**

Fr. Tadaride d'Égypte; Ger. Ägyptische Bulldoggfledermaus

Tadarida aegyptiaca (E. Geoffroy, 1818). Descrip. de L'Égypte 2: 128. Giza, Egypt.

Taxonomy Originally *Nyctinomus aegyptiacus*. Subgenus *Tadarida*. Synonyms in Africa: *anchietae*, *bocagei*, *brunneus*, *geoffroyi*, *talpinus*, *tongaensis*. Subspecies in Africa: two. Chromosome number (Kenya): 2n = 48; aFN = 54 (Nagorsen *et al.* 1976); (South Africa) 2n = 68 (Rautenbach *et al.* 1993).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral

membrane; medium-sized for an African molossid; ears of medium relative size, with inner margins almost meeting to form V-shaped valley; M³ with second and third ridges equal in length, anterior palatal emargination wide; wings dark; ventral flank-stripe in contrasting colour sometimes present; two lower incisors on each side. Sexes similar. Pelage short (mid-dorsal hairs 5–6 mm), sometimes glossy. Dorsal pelage grey, greyish-brown, reddish-brown, blackish-brown or black, often darker on head and flanks; no spots; hairs mostly

niveiventer</i> |
| | 41–46 | Medium brown to dark
grey | Deep
(Large) | Males with paired glands between penis and anus
Ventral pelage white or very pale
Crown darker than back
Phalanges of 3rd and 4th fingers short (see profile) | <i>T. (M.)
demonstrator</i> |
| | 59–67 | Dark brown | Moderate
(Medium to large) | Dorsal pelage colour variable; frosted and flecked | <i>T. (M.) midas</i> |
| | ca. 52 | Dark brown | Deep
(Large) | This combination of characters appears to be unique | <i>T. (M.) niangarae</i> |

unicoloured but some have a slightly paler tip giving pelage a silvered or frosted appearance in some individuals. Ventral pelage slightly paler mid-ventrally, becoming same as dorsal colour on flanks, sometimes grizzled; no mid-ventral markings; ventral flank-stripe same as dorsal colour or distinctly paler or, exceptionally, white. Orange-phase not known. Head not extremely flattened. Upper lip with ca. five well-defined wrinkles on each side and comparatively few spoon-hairs. Ears blackish-brown, of medium relative length (just reaching tip of snout when laid forward); inner margins almost meeting on muzzle to form V-shaped valley. Tragus large, subrectangular, not concealed by antitragus. Antitragus ca. twice size of tragus, roughly semi-circular. No interaural crest. Gular gland present in both sexes. Wings and interfemoral membrane brown and semi-translucent, or blackish-

brown. Ventral sides of forearms and legs naked and whitish. Foot with raised pad on sole (plantar pad).

Skull low but not extremely dorsoventrally flattened. Anterior of braincase not elevated (or only very slightly elevated) above plane of rostrum (as in Figure 99h). Sagittal crest absent or poorly developed; lambdoid crest poorly developed. Anterior palatal emargination wide. Interdental palate tapering slightly but evenly towards incisors. Basisphenoid pits moderate in depth, their width ca. equal to their distance apart. Anterior upper premolar ca. same height as cingulum of posterior premolar or lower; within toothrow. M³ with second and third ridges equal in length. Two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged, not in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Two subspecies occur in Africa (Koopman 1994):

T. a. aegyptiaca: African range excluding W Zambia, Angola, Namibia. Slightly larger; paler.

T. a. bocagei: W Zambia to Angola and Namibia. Slightly smaller; darker.

Similar Species Four other *Tadarida* in Africa have ears with inner margins meeting, or almost meeting, to form a V-shaped valley:

Tadarida fulminans. Larger (FA: 56–61 mm; GLS: 21.6–24.4 mm).

Wings ventrally whitish. Ventral pelage with a white, cream or yellowish mid-ventral band and ventral flank-stripe.

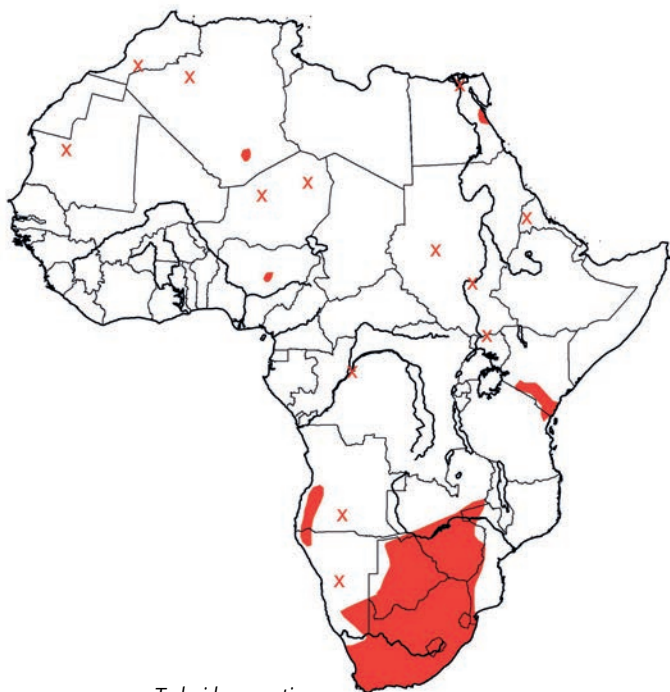

T. lobata. Usually larger (FA: 55–62 mm; GLS: 22.3–23.6 mm).

Inner margins of ears meeting close to snout; ears extending well beyond snout when laid forward. White spot between shoulder-blades of adults.

T. teniotis. Three lower incisors on each side. Larger (FA: 58–64 mm; GLS: 22.5–24.8 mm). North Africa.

T. ventralis. Much larger (FA: 60–67 mm; GLS: 23.4–26.1 mm).

Distribution In Africa, recorded disjunctly from Nile Delta, Red Sea coast and scattered inland localities in the Sahara Arid BZ, from a few scattered localities in the Sudan Savanna BZ, and from one locality in the Rainforest BZ, but mostly recorded from Somalia–Masai Bushland, Coastal Forest Mosaic, Zambezan Woodland, Highveld, South-West Arid, South-West Cape and Afromontane–Afroalpine BZs. Recorded from Morocco, Algeria, Egypt, Niger, Nigeria, Sudan, Ethiopia, DR Congo and Kenya, and all countries southwards except, as yet, Malawi. Extralimitally: Saudi Arabia, Yemen and Oman and beyond to Afghanistan, India and Sri Lanka. Mapped from country checklists (see order Chiroptera), other literature and museum records. Subsequently recorded from E Uganda (Thorn & Kerbis Peterhans 2009): not mapped.

Habitat In Africa, mostly recorded from open woodland and bushland savannas (including undifferentiated woodlands, *Acacia–Commiphora* bushland, miombo and mopane woodlands), arid scrublands, open grasslands and forest-dominated valley bushveld (Smithers 1983, Taylor, P. 1998). Also found in some very arid areas but probably only where drinking water, insects and suitable day-roosts are available; e.g. in arid Botswana, associated with waterholes, bore-holes, reservoirs and temporary pools (Smithers 1983). Frequently occupies built-up areas (Taylor, P. 1998, R. T. F. Bernard pers. obs.). The record in rainforest is probably that of a vagrant.

Abundance Abundant in some parts of geographic range, particularly in southern Africa where day-roosts may contain thousands of individuals (R. T. F. Bernard pers. obs.). Apparently restricted to a very limited range of localities in Angola and Zambia (Smithers 1983).

Adaptations Aspect ratio very high; wing-loading medium, lower than in most molossids (Norberg & Rayner 1987). Predicted to fly more slowly than most molossids (Norberg & Rayner 1987). Scuttles and climbs very adeptly over horizontal to vertical surfaces. Day-roosts include narrow horizontal and vertical crevices in rockfaces and buildings, cracks under exfoliating rocks, behind bark of *Acacia* trees, cracks in tree-trunks, hollow trees, roofs of houses and churches (often between tiles and insulation or between tiles and rafters), crevices and crannies within caves (Shortridge 1934, Rautenbach 1982, Smithers 1983, Taylor, P. 1998). Clings in contact with substrate, usually tucked into narrow cracks and crevices. Occasionally reported roosting with *T. pumila*, once with both *T. pumila* and *Otomops martiensseni*, and once with *Pipistrellus capensis* (Herselman & Norton 1985, Taylor, P. 1998). Can tolerate extreme roost temperatures, e.g. under corrugated iron roof in South Africa, below zero in winter to above 45 °C in summer (R. T. F. Bernard unpubl.). There is no evidence, from observations in laboratory and field, that this species enters torpor or hibernation (Bernard unpubl.). Specimens from Western Cape, South Africa, captured late Jan to early Feb, had yellow fat at base of ribs and hips, suggesting an increase in body fats before winter (Seamark 2005).

Foraging and Food Forages by fast-hawking. Observed flying high, and also skimming over water to pick up water-beetles and other aquatic insects or to sip water (Shortridge 1934, Smithers 1971). Based on remains in faeces, diet includes beetles and moths (Fenton & Thomas 1980, Fenton 1985).

Echolocation Call-shape variable. Search-phase call-shape: quasi-linear shallow FM. Search-phase (Zimbabwe): start-frequency 26 kHz; end-frequency 15 kHz; peak-frequency 18 kHz; maximum call-duration 15 ms; intensity high (five bats, flying in open; Fenton & Bell 1981). Search-phase (South Africa): start-frequency (mean \pm S.D.) 23.2 ± 1.9 kHz; end-frequency 18.7 ± 1.3 kHz; call-duration 7.0 ± 2.6 ms, sometimes up to 12 ms; energy mainly in fundamental harmonic but up to three harmonics may be present (three bats, flying in open; Taylor 1999a, 2000). When scuttling, call-shape similar but steeper; start-frequency ca. 29 kHz; end-frequency ca. 18.6 kHz; duration ca. 5.5 ms (Taylor 1999a).

Social and Reproductive Behaviour Occasionally roosts singly or in pairs, more often in groups of up to 50 or more, and sometimes in colonies of several hundreds (Shortridge 1934, Rautenbach 1982, Taylor, P. 1998) and even thousands (R. T. F. Bernard pers. obs.). Much noisy squeaking and chirping (audible to humans) occurs in the roosts prior to emergence of these bats at dusk. Maternity colonies are formed in summer in South Africa (Taylor 2000, R. T. F. Bernard pers. obs.).

Reproduction and Population Structure Litter-size: one. At ca. 33°S in South Africa, the reproductive chronology is restricted seasonal monoestry with copulation in Aug and parturition in early summer (Nov–Dec) after 4-month gestation (Bernard & Tsita 1995). Right ovary and right uterine horn significantly larger than on left; corpora lutea in right ovary only; pregnancies in right uterine horn only. Climate of study area is strongly seasonal, with a single hot and typically wetter season from Oct–Apr, and a cool, drier season from May–Sep. Monoestry at this high latitude is probably explained by the comparatively long gestation and the relatively short period during which temperatures are high enough to ensure abundant insects. In contrast, at 24°S where temperatures are higher for longer, *T. pumila* and *T. condylura* have shorter gestations and are polyoestrous (see profiles). There appear to be no conclusive data for *T. aegyptiaca* elsewhere in Africa. In Zimbabwe, pregnant ♀♀ were caught in Nov and lactating ♀♀ in Dec (no data given for other months) (Smithers & Wilson 1979). In South Africa, ♂♂ apparently reach sexual maturity in second year; ♀♀ in first year.

Predators, Parasites and Diseases Remains have been found in pellets of Barn Owls *Tyto alba* in the West Coast N. P., South Africa (Avery 1992). Ectoparasites include bed-bugs *Striticimex transversus*,

S. namru (Hemiptera: Cimicidae); fleas *Araeopsylla gestroi*, *A. scitula*, *A. wassifi*, *Chiropteropsylla brockmani* (Siphonaptera: Ischnopsyllidae); ticks *Carios vespertilionis*, *C. boueti*, *C. confusus* (Acari: Argasidae); and mites *Parasteatonyssus nyctinomi*, *P. cornutus* (Acari: Macronyssidae), *Microtrombicula kanyei* (Acari: Trombiculidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Tadarida aloysiisabaudiae DUKE OF ABRUZZI'S FREE-TAILED BAT

Fr. Tadaride d'Aloys Sabaud; Ger. Fürst von Abruzzen Bulldoggfledermaus

Tadarida aloysiisabaudiae (Festa, 1907). Boll. Mus. Zool. Anat. Comp. Univ. Torino 22 (546): 1. Toro, W Uganda.

Taxonomy Originally *Nyctinomus Aloysii-Sabaudiae*. Subgenus *Chaerephon*. Synonyms: *cyclotis*. Subspecies: none recognized here (see Geographic Variation). Chromosome number (Cameroon): 2n = 48; aFN = 66 (Smith *et al.* 1986). The name *aloyisabaudiae* is a latinization of one of the names and titles (Luigi di Savoia) of the Duke of the Abruzzi who led the Italian Rwenzori expedition during which this bat was first collected. Savoy was known to the Romans as Sabaudia (Hayman & Hill 1971). Considered to be closely related to *T. russata* by Peterson (1967, 1969, 1971a) and Fenton & Peterson (1972). Possibly also closely related to *T. bivittata* and *T. ansorgei* (Freeman 1981).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears joined by interaural band; M³ with third ridge > half length of second ridge; anterior palatal emargination closed; wings blackish-brown; ventral flank-stripe not in contrasting colour; no tail-glands; rostrum uniquely narrow and elongated; FA: 48–53 mm. Sexes similar.

Pelage short (mid-dorsal hairs ca. 4 mm), sparse on nape; dorsal pelage extending over rump and onto interfemoral membrane. Dorsal pelage chocolate brown to dark rusty-brown (orange-phase: bright rusty-orange), sometimes with small, diffuse whitish spots or scattered whitish hairs; all dorsal hairs pale at base. Ventral pelage with flanks dark brown, belly similar to dorsal pelage but paler and suffused with greyish-fawn; no mid-ventral markings; ventral flank-stripe same colour as flanks. Head not extremely flattened; dorsal surface of snout inconspicuously covered with short, stiff bristle-like hairs. Upper lip with 8–9 well-defined wrinkles on each side and many spoon-hairs. Ears blackish-brown, broad, not quite reaching snout when laid forward; inner margins joined by interaural band across forehead, which projects forward as a knob-like protuberance (containing a backward-opening interaural pocket) that almost covers the snout. Tragus small, tip bluntly pointed, concealed by antitragus. Antitragus well developed, roughly semi-circular. Interaural crest of dark brown hairs arising from interaural pocket in both sexes. No gular gland. Wings and interfemoral membrane blackish-brown. For additional information, see Lanza & Harrison (1963).

Skull large and elongated with a long, narrow rostrum; not extremely dorsoventrally flattened. Anterior of braincase slightly but distinctly elevated above plane of rostrum. Sagittal and lambdoid crests weakly developed or absent. Anterior palatal emargination closed; two foramina, and usually also a third, median foramen behind the incisors. Basisphenoid pits deep, large, their width more than twice their distance apart. Anterior upper premolar distinctly taller than cingulum of posterior premolar, within toothrow; canine and posterior upper premolar well separated. M^3 with third ridge almost as long as second ridge. Two lower incisors on each side; bicuspid, crowded. Lower canines with cingula not greatly enlarged, not in contact. Anterior lower premolar ca. equal in size to posterior premolar in ♂♂, but smaller than posterior premolar in ♀♀. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded but data are limited. Grubb *et al.* (1998) provisionally listed *cyclotis* Brosset, 1966 as a subspecies, but this view is not held by Hayman & Hill (1971), Fenton & Peterson (1972) and Simmons (2005), and is not held here.

Similar Species Four other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge > half length of second; wings neither white nor whitish; no ventral flank-stripe in contrasting colour; no tail-glands (Table 20, p. 488):

Tadarida ansorgei. Smaller (FA: 43–48 mm; GLS: 18.6–20.5 mm).

Wings semi-translucent light reddish-brown to light grey. Interaural band comparatively less prominent and with V-shaped fold in middle. Skull with anterior palatal emargination narrow (bulb-shaped). Basisphenoid pits moderate in depth, small, their width less than their distance apart.

T. bivittata. Often with white spots and sometimes short stripes on head and neck; dorsal pelage not extending on to interfemoral membrane. Ears on average smaller; not reaching snout when laid forward. Interaural band comparatively less prominent and with V-shaped fold in middle. Skull with anterior palatal emargination narrow (bulb-shaped). Basisphenoid pits moderate in depth, small to medium-sized, their width \leq their distance apart.

T. russata. Smaller (FA: 42–46 mm). Skull shorter (GLS: 17.8–19.4 mm) and narrower (GWS: 10.5–11.4 mm). Otherwise very similar in pelage pattern and colour as well as in external characters.

T. pumila (sometimes). Much smaller (FA: 32–39 mm; GLS: 14.2–17.6 mm).

Distribution Endemic to Africa. Recorded mainly from Rainforest BZ (Western, West Central and East Central Regions) and adjacent Northern and Eastern Rainforest–Savanna Mosaics, with one record very marginally in Sudan Savanna BZ on the upper Mountain Nile R. (Bahr al Jabal) in S Sudan. Known from 16 localities in Côte d'Ivoire, Ghana, Cameroon, Gabon, Central African Republic (Boukoko, MNHN), DR Congo, Sudan (Juba, SMNS) and Uganda (Brosset 1966, Peterson 1967, 1969, 1972, Fenton & Peterson 1972, Smith *et al.* 1986, Beaucournu & Fahr 2003, J. Fahr unpubl.).

Habitat Mainly recorded from lowland rainforest, montane forest flanking the Albertine Rift Valley, swamp forest, and rainforest–

Tadarida aloysiisabaudiae

savanna mosaic adjacent to rainforest; also from one locality in flooded grassland (Juba, Sudan). One specimen was taken in a clearing within forest in Gabon, one from cutover rainforest in Ghana, others from 'Guinea woodland' in Ghana and Uganda, and others appear to have been taken in forested areas but without further details (Fenton & Peterson 1972). Fenton & Peterson (1972) suggested that this species 'may be associated with a forest-edge or semi-open forest habitat rather than with either dense high forest or with open forest or savannas', but this needs confirmation because it has now been captured within closed primary rainforest (J. Fahr unpubl.). Mainly recorded from lower altitudes, with 1200 m as the known maximum (Fenton & Peterson 1972). Individuals were mostly captured with mist-nets set over water or in forest clearings (Brosset 1966, Fenton & Peterson 1972, J. Fahr unpubl.).

Abundance Not known. Appears to be quite rare but surveys with elevated mist-nets are needed to determine accurately both the abundance and distribution of this species.

Remarks In Garamba N. P., NE DR Congo, one ♂ was taken from a fissure in the trunk of an *Isoberlinia doka* tree that was also inhabited by a colony of ca. 150 *T. condylura* (Verschuren 1957 as *T. (Mops) trevori* but re-identified by Peterson 1972). Like most other molossids, mainly forages by fast-hawking in open spaces above the vegetation. In forest-savanna vegetation in Comoé N. P., Côte d'Ivoire, the median height of captures (in mist-nets set 0–25 m above ground) was 17.0 (12.4–19.6) m ($n = 5$). In rainforest in Taï N. P., Côte d'Ivoire, two individuals were mist-netted between 1–3 m over small creeks, but they had probably descended to drink.

Predators, Parasites and Diseases Ectoparasites include a flea *Lagaropsylla senckenbergiana* (Siphonaptera: Ischnopsyllidae) (Beaucournu & Fahr 2003).

Conservation IUCN Category: Least Concern.

Only 16 localities; seems comparatively rare. Major threats: loss and degradation of habitat mainly because of logging and agriculture. Population trend inferred to be declining.

Tadarida ansorgei ANSORGE'S FREE-TAILED BAT

Fr. Tadaride d'Ansorge; Ger. Ansorges Bulldoggfledermaus

Tadarida ansorgei (Thomas, 1913). Ann. Mag. Nat. Hist., ser. 8, 11: 318. Malanje [= Malange], Angola.

Taxonomy Originally *Nyctinomus ansorgei*. Subgenus: placed in *Chaerephon* (e.g. by Koopman 1994 and Simmons 2005) but previously placed in subgenus *Tadarida* by some authors (e.g. Hayman & Hill 1971). Synonyms: *rhodesiae*. Subspecies: none. Appears closely related to the often sympatric *T. bivittata* (Eger & Peterson 1979), but the *ansorgei/bivittata* complex needs further revision (see profile of *T. bivittata*). *Tadarida bivittata* currently appears to contain a form that resembles *T. ansorgei*, and some information in the literature attributed to *T. bivittata* probably refers to *T. ansorgei*, and vice versa. Furthermore, museum collections probably contain misidentified specimens. Chromosome number (Cameroon): 2n = 48; aFN = 66. X = medium-sized subtelocentric, Y = small acrocentric (Smith *et al.* 1986). In South Africa: 2n = 48; aFN = 68. X = medium metacentric, Y = small acrocentric (Rautenbach *et al.* 1993).

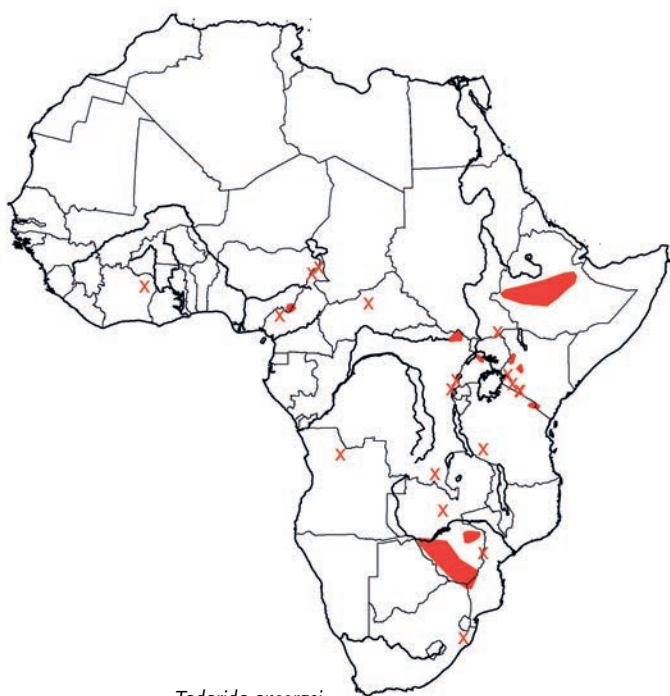

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears joined by interaural band; M³ with third ridge > half length of second ridge; anterior palatal emargination narrow; dorsal pelage dark greyish-brown to reddish-brown (occasionally spotted); wings light grey or reddish-brown; no ventral flank-stripe in contrasting colour; no tail-glands. Not easily distinguished from *T. bivittata*. Sexes similar in colour; ♂♂ slightly larger on average than ♀♀. Pelage short (mid-dorsal hairs ca. 4 mm), soft, dense, sparse on crown behind junction of ears and sometimes sparse on nape; terminates abruptly on rump. Dorsal pelage dark greyish-brown to chocolate brown or reddish-brown, somewhat frosted and occasionally with white spots; hairs unicoloured or with pale grey at tip. Based on museum specimens, greyish-brown individuals more common (cf. *T. bivittata*). Ventral pelage paler than dorsal pelage except on throat, which is blackish to brown, conspicuously darker and denser than elsewhere, especially in ♂♂. Chin naked, in marked contrast with dense pelage on throat. No mid-ventral markings; no ventral flank-stripe in contrasting colour; pelage not extending onto wing-

membrane. Head not extremely flattened. Upper lip with 6–7 well-defined wrinkles on each side and many spoon-hairs. Ears pale-grey to reddish-brown, reaching ca. half-way along muzzle when laid forward; inner margins joined by interaural band with V-shaped fold in middle. Tragus very small, subquadrangular; antitragus much larger and roughly trapezoid (widest at base). Interaural crest of dark hairs (ca. 2 mm) in shallow pouch, in both sexes; denser and more conspicuous in ♂♂. Gular gland: no information. Wings semi-translucent light reddish-brown to light grey dorsally and ventrally; interfemoral membrane slightly darker.

Skull not extremely dorsoventrally flattened. Anterior of braincase only slightly elevated above plane of rostrum (frontals inflated dorsally into a very shallow dome, Figure 99e) (cf. *T. bivittata*). Mastoid width: 10.8 (10.2–11.2) mm, n = 139 (sexes alike) (cf. *T. bivittata*) (Eger & Peterson 1979). Sagittal crest distinct although very low, and usually complete (extending unbroken across whole braincase), but in 7% of 60 specimens from DR Congo (RMCA) the crest does not extend across the posterior third of the cranium, and in 3%, it is very indistinct over this section. Lambdoid crests moderate. Anterior palatal emargination narrow, bulb-shaped (narrowest between incisors). Basisphenoid pits moderate in depth, small, their width less than their distance apart. Anterior upper premolar ca. same height as cingulum of posterior premolar, within toothrow; canine and posterior premolar separated. M³ with third ridge almost as long as second ridge. Two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged, usually almost in contact, occasionally in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Four other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge > half length of second; wings neither white nor whitish, no ventral flank-stripe in contrasting colour; no tail-glands (Table 20, p. 488):

*Tadarida ansorgei*

Tadarida aloysiisabaudiae. Larger (FA: 48–53 mm; GLS: 20.0–22.3 mm). Wings blackish-brown. Interaural band comparatively prominent, with knob-like projection almost covering snout. Skull with anterior palatal emargination closed. Basisphenoid pits deep, large, their width more than twice their distance apart.

T. russata. Dorsal pelage uniformly dark rusty-brown to sepia brown; no grizzling, no white flecks or spots; hairs with paler bases. Skull with anterior of braincase moderately elevated above plane of rostrum. Anterior palatal emargination closed. Basisphenoid pits moderate in depth, separated by narrow bony ridge (< half breadth of one pit).

T. bivittata. Dorsal pelage often (but not always) with white stripes or rows of spots on head and neck. Wings dark brown or reddish-brown. Ears broader and dorsally browner. More robustly built (see weights). Skull with anterior of braincase moderately elevated above plane of rostrum. Mastoid width greater. Sagittal crest sometimes incomplete. A classification coefficient for distinguishing *T. bivittata* is given by Eger & Peterson (1979).

T. pumila (sometimes). Much smaller (FA: 32–39 mm; GLS: 14.2–17.6 mm).

Distribution Endemic to Africa. Mainly recorded from Eastern Rainforest–Savanna Mosaic, Somalia–Masai Bushland BZ and Afromontane–Afroalpine BZs in NE DR Congo, S Sudan, Ethiopia and East Africa, and from the Zambezian Woodland BZ from SE DR Congo through Zambia and Zimbabwe to KwaZulu–Natal (South Africa). There is also an apparently isolated record from Guinea Savanna BZ in Côte d’Ivoire and another in Southern Rainforest–Savanna Mosaic in N Angola (Eger & Peterson 1979, Hill 1983, Nikolaus & Dowsett 1989, Bouchard 2001).

Habitat Mainly woodland savannas (including *Isoberlinia* woodland, *Acacia*–*Commiphora* bushland and miombo woodland), and montane habitats (no details available). In Zimbabwe, recorded from dry

woodland savanna in the vicinity of rugged hills and mountain ranges with rock cliffs and precipices.

Abundance Locally common in Zimbabwe; some roosts accommodate hundreds of individuals.

Adaptations Aspect ratio high to very high; wing-loading medium. Flight fast and agile. Scuttles rapidly; scrambles backwards into small crevices. Most often roosts by day in small crevices that are high up in cracks and clefts in cliffs and rocky hills; also roosts in crevices inside caves, mine-adits and occasionally buildings, and in expansion joints high up in concrete bridges. Near Faradje, NE DR Congo, a colony roosted, in total darkness, in a crack in a hill rising ca. 60 m above the surrounding bushveld (Lang & Chapin 1917b). The accumulation of 30 cm of guano in this day-roost indicated long-term residence. However, day-roosts in Zimbabwe are sometimes temporarily abandoned; departures do not appear related to seasonal changes, and it is not known if the bats move into nearby day-roosts, or migrate further afield (F. P. D. Cotterill unpubl.). In NE DR Congo, sometimes shares roosts with *T. major* (Verschuren 1957). In Zimbabwe, sometimes shares roosts with *T. bivittata* (flocks of both species emerge together) and *T. fulminans* (Cotterill & Fergusson 1993a).

Foraging and Food Forages by fast-hawking. Flocks were observed leaving roost at dusk and flying fast to a considerable altitude (R. A. Fergusson pers. comm.). Stomachs of two individuals from DR Congo contained legs of beetles, wings of Formicidae (?) and antennae of Hymenoptera (?) (Verschuren 1957).

Echolocation Search-phase call-shape (Zimbabwe): shallow FM. Start-frequency 28 kHz; end-frequency 16 kHz; bandwidth 16–28 kHz; peak-frequency 17.8 kHz; maximum call-duration 15 ms (five bats flying in open; Fenton & Bell 1981).

Social and Reproductive Behaviour In NE DR Congo, found roosting in groups (colonies) of no more than 30–40 individuals; ♂♂ and ♀♀ in approximately equal numbers; no segregation of sexes observed (Verschuren 1957). In Zimbabwe, usually roosts in colonies of up to many hundreds. Within roosts, groups of bats huddle tightly together in nooks and crannies, but are often restless and can be heard squeaking and jostling. Samples of bats taken from roosts in Zimbabwe contained more ♂♂ than ♀♀.

Reproduction and Population Structure Litter-size: one ($n = 10$). At 16–18°S in Zimbabwe, the reproductive chronology appears to be seasonal bimodal polyoestry without postpartum oestrus, with births at beginning of hot-wet season (Nov) and at end of hot-wet season (Apr), but this needs confirmation. This is based on the following observations: ten ♀♀ pregnant and near term in Oct (crown–rump length of embryos 25 [21–29] mm); lactating ♀♀ found in Nov–Dec and also in Apr (no data for other months) (F. P. D. Cotterill unpubl.). Polyoestry is indicated by lactating ♀♀ collected in late Dec and mid-Jan, each of which had a fully developed Graafian follicle in the right ovary.

Predators, Parasites and Diseases Skulls have been recovered from pellets of Barn Owls *Tyto alba*, and Mackinder’s Eagle-owls *Bubo*

capensis have been observed hawking molossidids emerging from their roosts in Zimbabwe (Cotterill 1992). *Tadarida ansorgei* is collected from its day-roosts and eaten by people in DR Congo (Lang & Chapin 1917b). Ectoparasites include a flea *Lagaropsylla anciauxi* (Siphonaptera: Ischnopsyllidae) and mites *Chelanyssus spiniferus* (Acari: Macronyssidae), *Alabidocarpus molossicola* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Tadarida bemmeleni GLAND-TAILED FREE-TAILED BAT

Fr. Tadaride à glande caudale; Ger. Schwanzdrüsen-Bulldoggfledermaus

Tadarida bemmeleni (Jentink, 1879). Notes Leiden Mus. 1: 125. Liberia (no specified locality).

Taxonomy Originally *Nyctinomus bemmeleni*. Sometimes incorrectly spelled *bemmelini*. Subgenus *Chaerephon*. Synonyms: *cistura*. Subspecies: two currently recognized (but see Geographic Variation). Possibly includes more than one species. The species was described from a specimen from Liberia. Later, Jentink (1888) stated that the specimen had been received in 1875 through the Zoological Garden Rotterdam, which led subsequent authors to question Liberia as the type locality. However, recent specimens from Liberia, Sierra Leone and Côte d'Ivoire support the Liberian origin of the holotype. According to Freeman (1981), *T. bemmeleni* is rather distinct and basal within *Chaerephon* and, together with *T. ansorgei* and *T. bivittata*, connects this subgenus with the subgenus *Tadarida*. Seems to be most closely related to *T. bivittata* (Peterson 1971b, Freeman 1981). Chromosome number (Kenya): 2n = 48; aFN = 54 (Nagorsen *et al.* 1976).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears joined by low interaural band, M³ with third ridge > half length of second; anterior palatal emargination narrow; wings pale grey, ventral flank-stripe whitish; distinguished from other molossidids by conspicuous tail-glands that open ventrally, one on each side of the base of the tail. Sexual dimorphism slight: on average, ♂♂ with longer second phalanx of third and fourth finger, longer skull and longer canines. Pelage short (mid-dorsal hairs ca. 4 mm); covering rump but not extending onto interfemoral membrane, which is clad only with very short, thin hairs. Dorsal pelage dark brown with slight frosting but no spots or stripes; hairs bicoloured with pale tip. Head same colour as dorsal pelage. Ventral pelage paler, flanks darker than belly; hairs pale brown with whitish or greyish tips; no mid-ventral markings; ventral flank-stripe whitish, contrasting with dark flanks. No black or darker pelage on throat. Head not extremely flattened. Upper lip with 6–8 well-defined wrinkles on each side and comparatively few spoon-hairs. Ears blackish-brown, very broad and squarish in

outline, reaching snout when laid forward; inner margins joined by low interaural band with V-shaped fold in middle. Tragus small and concealed by antitragus. Antitragus large. Interaural band without distinct crest, sometimes with dense hairs, sometimes almost naked. No gular gland. Wings and interfemoral membrane pale grey. Forearm and third metacarpal dorsally clad with very short, fine hairs, giving a velvety appearance. Both sexes with longitudinal sac-like tail-glands that open ventrally on either side of the tail just posterior to its junction with the body (Figure 111). Sometimes these glands are also dorsally visible as paired swellings, one on each side of the base of the tail.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly to moderately raised above plane of rostrum. Sagittal crest weakly developed; lambdoid crest moderate. Anterior palatal emargination narrow. Basisphenoid pits shallow, their width ca. equal to their distance apart. Anterior upper premolar slightly higher than cingulum of posterior premolar, within tooththrow. M³ with third ridge ca. three-quarters to almost same length as second. Two lower incisors on each side, slightly to clearly crowded. Lower canines with cingula not greatly enlarged, not in contact. Dental formula: $1^{123}/_{2123} = 30$.

Figure 111. The unique tail-glands of *Tadarida bemmeleni*. (a) Dorsal view showing paired swellings associated with the glands, one on each side of the base of the tail. (b) Ventral view showing the two longitudinal openings of the glands. Based on Peterson (1971b).

Geographic Variation Two subspecies are currently recognized (e.g. Peterson 1971b, Koopman 1975, Simmons 2005):

T. b. bemmeleni: Guinea, Sierra Leone, Liberia, Côte d'Ivoire and Cameroon. On average smaller (FA: 43.8 [41–46] mm, $n = 34$; Tib: 13.3 [12–15] mm, $n = 34$; GLS: 17.3 [16.6–18.1] mm, $n = 24$).

T. b. cistura: E DR Congo, S Sudan, SW Kenya and N Tanzania. On average larger (FA: 46.0 [43–48] mm, $n = 9$; Tib: 13.9 [13–15] mm, $n = 6$; GLS: 18.3 [17.8–18.9] mm, $n = 8$).

The apparent disjunction between the distributions of these taxa, together with differences in size (especially in FA, tibia and craniodental measurements), skull morphology (braincase higher, lachrymal breadth of rostrum greater and width across upper canines greater in *T. b. cistura*; see Peterson 1971b) and habitat preferences, suggest that these taxa might be distinct species, but further material, especially from West Africa, is needed to resolve this question.

Similar Species No other African molossid has conspicuous sac-like tail-glands that open ventrally, one on each side of the base of the tail (sometimes also visible dorsally as paired swellings).

Distribution Endemic to Africa. *Tadarida b. bemmeleni* is known from only five localities in Rainforest BZ (Western and West Central Regions), Afromontane–Afroalpine BZ and Northern Rainforest–Savanna Mosaic. Recorded from Sierra Leone, Liberia, Côte d'Ivoire (Duékoué; Taï N. P.) and Cameroon (Peterson 1971b, J. Fahr unpubl.). A record from Marshall Territory near Harbel, Liberia, published by Bray (1958) as *T. bemmeleni*, was later referred to *T. brachyptera* by Koopman (1989). *Tadarida b. cistura* is more widely known from ca. 17 localities in Eastern Rainforest–Savanna Mosaic and Somalia–Masai Bushland BZ in S Sudan, E DR Congo, Uganda, SW Kenya and N Tanzania (Peterson 1971b, J. Fahr unpubl.).

Habitat *Tadarida b. bemmeleni* has been found in lowland rainforest and semi-deciduous forest (Liberia, Côte d'Ivoire), forest–savanna mosaic (Cameroon) and montane grassland (Mt Nimba). Recorded from lowlands to ca. 1600 m (Mt Nimba, Liberia; SMF). In Cameroon, individuals were mist-netted over a fast-running stream where it emerged from a forested area into a cleared area adjacent to a banana plantation (Peterson 1971b). One ♂ and one ♀ were captured on consecutive nights, at 13.6 and 10.8 m above the ground, in elevated mist-nets set over the clearing of a research station within Taï N. P., Côte d'Ivoire (S. Pettersson pers. comm.). *Tadarida b. cistura* has been recorded from drier vegetation zones such as *Acacia–Commiphora* bushland, *Isoberlinia* woodland and forest–savanna mosaic. Most specimens have been caught in mist-nets over rivers and streams. One from Budongo Forest, Uganda, was mist-netted over a dam at the edge of a forest; another was taken from a hole in some rocks on the side of a gorge at 1600 m near Kampala, Uganda, and another from the slopes of Mt Kilimanjaro, Tanzania. Possibly rocky outcrops are required for roosting (Peterson 1971b).

Abundance Uncertain. Apparently localized and probably fairly rare (especially the western subspecies), but data are not sufficient for accurate assessment.

Tadarida bemmeleni

Remarks Body mass appears to be relatively low for the size of this bat, possibly indicating a particular foraging strategy. Start (1969) found four individuals exhausted in a swimming pool: probably they became trapped after descending to drink from the pool. No other molossid in Africa has tail-glands: the cellular structure and function of these glands is not known. In Tanzania, one specimen was recovered from pellets of a Barn Owl *Tyto alba* (SMF). Ectoparasites include a mite *Ewingana hispinosa* (Acari: Myobiidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

If *T. b. bemmeleni* and *T. b. cistura* are found to be distinct species (see Geographic Variation), the appropriate IUCN Category for *T. bemmeleni* would be 'Near Threatened' or 'Data Deficient' based on its limited area of occupancy, which is very fragmented and degraded. For *T. cistura*, 'Least Concern'.

Tadarida bivittata SPOTTED FREE-TAILED BAT

Fr. Tadaride tachetée; Ger. Gefleckte Bulldoggfledermaus

Tadarida bivittata (Heuglin, 1861). Nouv. Act. Acad. Caes. Leop.-Carol., Halle 29 (8): 4, 13. Keren, Ethiopia.

Taxonomy Originally *Nyctinomus bivittatus*. Subgenus *Chaerephon*. Synonyms: none. Appears closely related to *T. ansorgei* (Eger & Peterson 1979). Contains more than one form. Heuglin described *T. bivittata* (on p. 13) from three umber brown specimens that have white markings (spots and/or stripes on head and neck) and dark brown wings and dark throats. As Heuglin did not designate a holotype, these specimens are considered to be syntypes (Hayman & Harrison 1966). Later (on p. 18), Heuglin referred to further specimens some of which are reddish-brown with almost no white markings (Hayman & Harrison 1966). In Zimbabwe, there appears to be a smaller, dark-throated form with lightly pigmented wings, and a larger, browner form, with more white markings and darker wings, which is not dark-throated; both are found in the same day-roosts, and both are sympatric with *T. ansorgei* in some areas (F. P. D. Cotterill pers. obs.). Although the relationship between *T. bivittata* and *T. ansorgei* was examined by Eger & Peterson (1979), it seems that the *ansorgei* / *bivittata* complex is in need of further revision to clarify the diagnostic characters of *T. ansorgei* and *T. bivittata*, and to ascertain if *T. bivittata* is polymorphic and/or contains cryptic species. Pending revision, some of the information below needs confirmation. Furthermore, museum collections probably contain some misidentified material, and the literature probably contains references to misidentified material. Chromosome number: $2n = 48$; $aFN = 54$. $X =$ subtelocentric; $Y =$ acrocentric (Peterson & Nagorsen 1975), but these authors reported difficulty in distinguishing between subtelocentric and acrocentric chromosomes.

Description Information not applicable to the syntypes is in brackets and marked with *. A small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears joined by interaural band; M^3 with third ridge $>$ length of second ridge; anterior palatal emargination narrow; dorsal pelage brownish (or reddish*), with white spots or stripes on head and neck (sometimes absent*); wings dark brown (or light reddish-brown*); no ventral flank-stripe in contrasting colour; no tail-glands. Not easily distinguished from *T. ansorgei*. Males slightly larger on average than ♀♀. Pelage short (mid-dorsal hairs 3–4 mm), soft, dense; sparse on crown; dorsal pelage covering rump but not extending on to interfemoral membrane (cf. *T. aloysiisabaudiae*). Dorsal pelage umber brown (or dark reddish-brown, greyish-brown to blackish-brown*), with rows of white spots and sometimes short stripes on crown, neck and back (or with almost no such markings*). Based on museum

specimens, reddish-brown individuals appear to be more common (cf. *T. ansorgei*) (Eger & Peterson 1979). It is not yet clear if these variations in colour and markings indicate polymorphism or cryptic species or perhaps both (see Taxonomy). Ventral pelage brown, often slightly frosted (especially on belly) and with or without pale speckling; no mid-ventral markings; ventral flank-stripe same colour as flanks and not extending onto the wing-membrane. Throat much darker than chest and belly (or similar in colour*). (Dark-throated specimens sometimes have, and sometimes lack, white spots and/or stripes*.) Head not extremely flattened. (Upper lip with 5–8 well-defined wrinkles on each side and many spoon-hairs [Freeman 1981, BMNH]*.) (Ears light reddish-brown, reaching about half-way along muzzle; inner margins joined by interaural band with V-shaped fold in middle*.) (Tragus very small, concealed by antitragus*.) (Antitragus large, roughly rectangular*.) Males with interaural crest of very short (ca. 2 mm) dark hairs. (No gular gland*.) Wings and interfemoral membrane dark brown (or wings light reddish-brown and interfemoral membrane slightly darker*).

Skull not extremely dorsoventrally flattened. Anterior of braincase moderately elevated above plane of rostrum (frontals inflated dorsally into a shallow dome, Figure 99d) (cf. *T. ansorgei*). (Mastoid width ♂♂: 11.7 [11.3–12.2] mm, $n = 71$; mastoid width ♀♀: 11.5 [11.0–11.9] mm, $n = 57$ [cf. *T. ansorgei*] [Eger & Peterson 1979]*.) Sagittal crest very low (and sometimes incomplete [i.e. with gap near middle of braincase]*). (Lambdoid crests moderate*.) Palate with small anterior vacuities (Hayman & Harrison 1966). (Anterior palatal emargination narrow, bulb-shaped [narrowest between incisors]*.) Basisphenoid pits moderate in depth, small to medium-sized, their width \leq their distance apart. Anterior upper premolar small (usually ca. same height as cingulum of posterior premolar but sometimes rising higher*), within toothrow; canine and posterior premolar well separated. M^3 with third ridge almost as long as second ridge. (Two lower incisors on each side, bicuspid, crowded*.) (Lower canines with cingula not greatly enlarged, well separated to almost in contact*.) Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None reported.

Similar Species Four other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge $>$ half length of second; wings neither white nor whitish; no ventral flank-stripe in contrasting colour; no tail-glands (Table 20, p. 488):

Tadarida aloysiisabaudiae. Dorsal pelage only sometimes spotted; extending on to interfemoral membrane. Ears on average larger; almost reaching snout when laid forward. Interaural band comparatively prominent, with knob-like projection almost covering snout. Skull with anterior palatal emargination closed. Basisphenoid pits deep, large, their width more than twice their distance apart.

T. russata. Smaller (FA: 42–46 mm; GLS: 17.8–19.4 mm). Skull with anterior palatal emargination closed, pair of incisive foramina visible. Basisphenoid pits moderate in depth, separated by narrow bony ridge (< half breadth of one pit).

T. ansorgei. Dorsal pelage occasionally spotted, sometimes frosted, but not with rows of spots or stripes on head and neck. Wings semi-translucent light reddish-brown to light grey. Ears narrower and pale grey to off-white. Less robustly built (see weights). Anterior of braincase less obviously elevated above plain of rostrum. Mastoid width smaller. Sagittal crest complete. A classification coefficient for distinguishing *T. ansorgei* is given by Eger & Peterson (1979).

T. pumila (sometimes). Much smaller (FA: 32–39 mm; GLS: 14.2–17.6 mm).

Distribution Endemic to Africa. Mainly recorded from Afromontane–Afroalpine, Somalia–Masai Bushland, Coastal Forest Mosaic and Zambezian Woodland BZs, with marginal records in Sahel Savanna and Sudan Savanna BZs and in Eastern Rainforest–Savanna Mosaic. Known from scattered localities on eastern side of Africa, from Eritrea and Ethiopia to Zimbabwe (*contra* Hutton 1986) and SW Mozambique (Koopman 1975, Eger & Peterson 1979, Smithers 1983, F. P. D. Cotterill unpubl.).

Habitat Mainly savanna woodlands (including dry *Acacia*–*Commiphora* bushland, and *Acacia* woodland in East Africa, and

miombo woodland in the south), and montane habitats in Eritrea, Ethiopia and Kenya. Occurs peripherally to the Congo Basin, but evidently not within it. At least in Zimbabwe, typically found near exposed rocky outcrops of granite, basalt and sandstone, which provide day-roosts.

Abundance Uncertain. In Zimbabwe, locally common in vicinity of day-roosts. At roosts shared with *T. ansorgei* and *T. bivittata*, *T. bivittata* is always captured in smaller numbers.

Remarks Very little is known, and some information in literature refers to *T. ansorgei*. Wings long and narrow. Flight and cursorial locomotion as in other *Tadarida*. By day, roosts high up in rock crevices and occasionally in buildings. Not known to roost in mines (*contra* Smithers 1983 whose record refers to *T. ansorgei*). Roosts in small groups or colonies; individuals huddle together in nooks and crannies. In Zimbabwe, shares roosts with *T. ansorgei*, but samples captured as these bats emerged always contained fewer *T. bivittata*. In these samples, ♂♂ outnumbered ♀♀ but the reason for this is not known – perhaps ♂♂ emerge earlier than ♀♀. Litter-size: no information. In Zimbabwe, pregnant ♀♀ have been reported in Oct and Nov, and reproductively inactive parous ♀♀ have been reported in late Mar. Skulls have been recovered from pellets of Barn Owls *Tyto alba* found below the day-roosts of the bats, and Mackinder's Eagle-owls *Bubo capensis* have been observed hawking molossids emerging from these day-roosts in Zimbabwe (Cotterill 1992). Ectoparasites include a flea (*Lagaropsylla anciauxi* [Siphonaptera: Ischnopsyllidae]) (Beaucournu & Kock 1996).

Conservation IUCN Category: Least Concern.

Tadarida brachyptera SHORT-WINGED FREE-TAILED BAT

Fr. Tadaride à ailes courtes; Ger. Kurzflügel-Bulldoggfledermaus

Tadarida brachyptera (Peters, 1852). Reise nach Mossambique, Säugeth., p. 59. Mozambique I. (15° S, 40° E), Mozambique.

Taxonomy Originally *Dysopes brachypterus*. Subgenus: *Xiphonycteris*. Synonyms: *leonis*, *ochraceus*. Subspecies: two of uncertain validity. Apparently closely related to *T. thersites* and some authors suggest that these forms might be conspecific (e.g. Rosevear 1965, Hayman & Hill 1971). Some authors (e.g. Freeman 1981) consider *leonis* (including *ochraceus*) to be a distinct species, but El-Rayah (1980, 1981) and Simmons (2005) treat *leonis* as conspecific. Chromosome number (Cameroon): $2n = 48$; $aFN = 54$; one pair large and three pairs medium metacentric and 19 pairs medium-small acrocentric autosomes (Smith *et al.* 1986).

Since this profile was submitted, a molossid from Pemba I. Tanzania, was described as *Mops (Xiphonycteris) bakarii* (Stanley 2008). This new species resembles *T. b. brachyptera* in size (FA: 35.9 [34–38] mm, $n = 21$; GSL: 19.3 [18.0–21.1] mm, $n = 13$), but differs mainly in that the basisphenoid pits are essentially absent and the anterior upper premolar barely extends above the cingulum of the canine. The new species is larger than *T. nanulus*, *T. petersoni* and *T. spurrelli*. It differs from *T. thersites* in lacking basisphenoid pits and having a much more reduced anterior upper premolar. There is no profile for this species and it is not mentioned in other profiles or tables. Further details in Appendix.

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 34–41 mm); ears joined by interaural band; M^3 with third ridge present but $<$ half length of second; anterior palatal emargination narrow, usually bulb-shaped; wings dark brown to black; ventral pelage pale, no ventral flank-stripe in contrasting colour; canines without greatly enlarged cingula. Not easily distinguished from *T. thersites*. Sexes similar. Pelage short (mid-dorsal hairs 3–4 mm), sometimes sparse on nape; dorsally there is either no band of naked skin, or only an inconspicuous narrow band of naked skin, adjacent to the flight-membranes (cf. wide band in *T. thersites*). Rump with two tufts of long hairs (as in several other species of *Tadarida*). Dorsal pelage blackish-brown, dark rusty-brown, sepia brown, or greyish-brown; no grizzling, no white flecks or spots; hairs dark brown with paler base. Orange-phase: bright orange-red specimens known from Cameroon. Ventral pelage pale brownish-grey, very pale grey, orange, yellowish-cream or white; mid-ventral marking inconspicuous or absent; ventral flank-stripe sepia brown or brownish-orange not contrasting with colour of flanks. Head not extremely flattened. Upper lip with 5–7 well-defined wrinkles on each side and many spoon-hairs. Ears blackish-brown, relatively small (not extending as far as snout when laid forward); inner margins joined by interaural band with V-shaped fold in middle. Tragus small. Antitragus large, subrectangular sometimes with corners very rounded. Interaural crest probably absent, but the posterior base of the interaural band often supports a tuft of dark brown, longer hairs. Gular gland: no information. Wings slightly translucent with heavy to light amounts of dark brown or black pigmentation. Wings inserting lower on body than in *T. thersites*. Interfemoral membrane dark brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase elevated above plane of rostrum (more so in *T. b. leonis* than in *T. b. brachyptera*; Freeman 1981). Sagittal crest absent, weakly developed or moderate depending on age. Lambdoid crest very well developed in both subspecies; helmet not quite so prominent as in *T. thersites* but more prominent than in *T. nanula*, *T. petersoni* and *T. spurrelli*. Anterior palatal emargination narrow, usually bulb-shaped (narrowest between incisors). Basisphenoid pits of moderate depth (*T. b. brachyptera*) or shallow (*T. b. leonis*) (Freeman 1981); their width slightly greater to much greater than their distance apart. Upper incisor not procumbent. Upper canines with cingula not enlarged; viewed laterally, incisor not obscured by canine (cf. *T. spurrelli*). Anterior upper premolar distinctly taller than cingulum of posterior premolar, within toothrow or slightly displaced labially. M^3 with third ridge much less than half length of second. Two lower incisors on each side, strongly bicuspid, crowded between canines. Lower canines long and robust; cingula not greatly enlarged, well separated. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Two subspecies are recognized by Koopman (1994) and Simmons (2005). Koopman (1994) proposed the following distributions for these subspecies:

T. b. leonis: Sierra Leone to E DR Congo.

T. b. brachyptera: Uganda to Mozambique; Zanzibar I.

The two widest gaps in the distribution of the species (see Map), especially that between the rainforest and coastal populations which is unlikely to be an artefact, do not seem to support the subspecific distributions proposed by Koopman (1994). If environmental factors (such as climate changes) have caused these two gaps, and if the gaps have resulted in subspeciation, it is more likely that there are three subspecies; *leonis* in the west, *ochraceus* in NE DR Congo and Uganda, and *brachyptera* in the Coastal Forest Mosaic BZ. However, this proposal needs further investigation.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge absent or present but $<$ half length of second; palatal emargination narrow; FA almost always < 40 mm (Table 20, p. 488):

Tadarida nanula. Forearm shorter (27–31 mm). M^3 with third ridge absent. Upper incisors procumbent (projecting in front of anterior faces of the canine cingula) (Figure 121).

T. petersoni. Usually smaller (FA: 32–35 mm; GLS: 15.8–17.4 mm). Skull without well-developed lambdoid crest. Canines shorter.

T. spurrelli. Forearm shorter (27–30 mm). M^3 with third ridge absent. Canines with greatly enlarged cingula; in lateral view, upper incisors obscured by upper canines (Figures 121 and 122).

T. thersites. Ventral pelage medium brown becoming very dark brown on flanks; ventral flank-stripe black. Dorsally, there

is a conspicuous, wide band of naked skin adjacent to flight-membranes. Wing insertion higher on body. Also, *T. bakarii* mentioned above in Taxonomy.

Distribution Endemic to Africa. Recorded, disjunctly, from Rainforest BZ and marginally from the Northern Rainforest–Savanna Mosaic, from Sierra Leone to SW Central African Republic (except in Dahomey Gap) and from NE DR Congo to Uganda (Budongo and Bugala I.: not mapped). An apparently separate population occurs in the Coastal Forest Mosaic BZ from Kenya to Mozambique, including Zanzibar I. (Neumann 1900) and Mozambique I. Said to occur on Mafia I. by Simmons (2005), but not recorded there by Moreau & Pakenham (1940), Cockle *et al.* (1998) or Kock & Stanley (2009). Said to occur in Gambia by Koopman (1993), but not recorded west of Sierra Leone according to Grubb *et al.* (1998). Reports of this species on Bioko I. (e.g. Koopman 1994) are considered erroneous by Eisentraut (1973) and J. Juste (pers. comm.). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Considered mainly a lowland rainforest species in West Africa (Rosevear 1965, Koopman *et al.* 1995), but also occurs along the rainforest–savanna ecotone and in the mosaic of lowland rainforest and secondary grassland. Not observed in primary rainforest in Gabon (Brosset 1966) and possibly occurs mainly in clearings and areas of invasive woodland savanna in and around

the Congolian rainforest, although a series from Budongo Forest, Uganda was collected when this was primary forest (ROM, J. Eger pers. comm.). Also occurs in the East African coastal forest mosaic, but was not found in any of the coastal forests investigated by Cockle *et al.* (1998) except Kiwengoma Forest.

Abundance Uncertain, but apparently common in some parts of geographic range.

Remarks Roosts by day in large hollow tree-trunks and hollow branches, deserted holes of barbets (Capitonidae) in dead trees, cracks in fabric of buildings and, very commonly, under corrugated iron roofs of houses. Large colonies are noisy and (to humans) pungently smelly; consequently regarded as pests. Sometimes roosts with *T. thersites*; less often with *T. condylura*. Recorded flying over water (Jones 1971). Known to eat winged termites (Lang & Chapin 1917b) but no other data available. Roosts in groups of 10–20 and in much larger colonies. Colonies reported to contain more ♀♀ than ♂♂ (Lang & Chapin 1917b). At 2–3°N in DR Congo, 14 of 18 ♀♀ had one medium-sized embryo (implanted in right uterine horn) in March (Lang & Chapin 1917b). Predators include Bat Hawks *Macheiramphus alcinus* (Chapin 1932).

Conservation IUCN Category: Least Concern.

If *leonis* is a distinct species, and even if it is retained as a subspecies, its conservation status should be assessed separately from that of *T. brachyptera* as it is probably much less common and widespread.

***Tadarida chapini* PALE FREE-TAILED BAT (CHAPIN'S FREE-TAILED BAT, LONG-CRESTED FREE-TAILED BAT)**

Fr. Tadaride de Chapin; Ger. Chapins Bulldoggfledermaus

Tadarida chapini (J. A. Allen, 1917). Bull. Amer. Mus. Nat. Hist. 37: 461. Faradje, Orientale, DR Congo.

Taxonomy Originally *Chaerephon* (*Lophomops*) *chapini*. Subgenus *Chaerephon*. Synonyms: *lancasteri*, *shortridgei*. Subspecies: three. Some authors consider *shortridgei* to be a distinct species (e.g. Peterson *et al.* 1995, Simmons 2005) but this view is not followed by Fenton & Eger (2002) and is not followed here. Chromosome number (Namibia, Zimbabwe): $2n = 48$; $aFN = 64$ (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 34–40 mm); ears joined by interaural band; M^3 with third ridge $>$ half length of second ridge; anterior palatal emargination closed or slightly open; wings white (tinged with yellow) with minute black spots; ventral pelage pure white or pale greyish-brown; ventral flank-stripe white; ♂♂ with a long, bicoloured interaural crest. Sexes similar except for crest. Pelage short (mid-dorsal hairs 4–5 mm), soft; covering rump but not extending onto interfemoral membrane. Dorsal pelage pale grey, pale rusty-brown or medium greyish-brown; no grizzling, no white spots; patch of whitish hairs on crown; mid-dorsal hairs pale rusty-brown with off-white at base. Ventral pelage pure white or pale greyish-brown; mid-ventral markings absent or white, usually a broad band; ventral flank-stripe white, only sometimes contrasting with ventral pelage. Head not extremely flattened; forehead slightly elevated. Upper lip with 5–6 wrinkles on each side and many spoon-hairs. Ears brown; of

medium relative size (just reaching snout when laid forward); inner margins joined by interaural band with deep, backward-opening, pocket-like invagination in middle. Tragus minute, partly concealed by antitragus. Antitragus moderately large, roughly trapezoid with front-side and base widest. Adult ♂♂ with conspicuous long bicoloured interaural crest arising from interaural pocket (Figure 112); hairs 12–15 mm with basal half rusty-red or grey, terminal half white (Allen 1917a). Adult ♀♀ with short tuft of white hairs. No gular gland. Wings usually white becoming yellowish near body or almost transparent with little white pigmentation; arm-wing with many minute black specks; dorsal skin over bones dark brown. A few specimens from Kenya have pale brown to greyish-brown wings (Fenton & Eger 2002). Interfemoral membrane medium brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum. Sagittal crest weakly developed. Lambdoid crests weakly developed or absent dorsally, moderately developed laterally. Anterior palatal emargination variable, can be closed or slightly open and narrow. Basisphenoid pits, moderate in depth, large, their width ca. twice their distance apart. Anterior upper premolar distinctly taller than cingulum of posterior premolar, within toothrow; canine and posterior premolar separated. M^3 with third ridge from just over half to ca. three-quarters the length of the second ridge. M^3-M^3 : 43.1 (41–44)% of GLS, $n = 11$ (cf. *T. pumila*). One or two lower incisors on each side (depending on locality); bicuspid, sometimes crowded. Lower canines slender and relatively short, with cingula not greatly enlarged and not in contact. Dental formula: $^{1123}/_{2123} = 30$ or (rarely) $^{1123}/_{1123} = 28$. For additional information see Fenton & Eger (2002).

Geographic Variation Three subspecies are recognized by Koopman (1994):

T. c. chapini: Ethiopia to DR Congo. Ventral pelage greyish-brown.

T. c. lancasteri: NE Angola to Botswana and Zimbabwe. Ventral pelage pure white.

T. c. shortridgei: SW Angola, NW Namibia. Ventral pelage greyish-brown.

The West African material has not been allocated.

Similar Species Only one other African *Tadarida* has the following combination of characters: ears joined by interaural band; M^3 with third ridge $>$ half length of second; no paired tail-glands at base of tail; FA: <40 mm (Table 20, p. 488):

Tadarida pumila. Dorsal pelage not pale brown; arm-wing dark or white without black specks; ♂♂ with short unicoloured interaural crest. M^3-M^3 relatively wider (45.5 [44–48]% of GLS, $n = 27$).

Distribution Endemic to Africa. Recorded from Guinea Savanna BZ in Côte d'Ivoire (J. Fahr pers. comm.), Ghana and S Sudan, from

Figure 112. The long, bicoloured interaural crest of *Tadarida chapini*. (a) Lateral view based on photo in which details of face and ear are obscure. (b) Dorsal view (BMNH 52.1505, *T. c. lancasteri*, Zambia). (c) Dorsal view showing crest erected (BMNH 66.6036, *T. c. lancasteri* incorrectly labelled *T. pumila*, Zambia).

*Tadarida chapini*

Rainforest–Savanna Mosaic in NE DR Congo and Uganda, from Somalia–Masai Bushland BZ in Ethiopia and Kenya, and from the Southern Rainforest–Savanna Mosaic and Zambezian Woodland BZ in Angola, SW DR Congo, Zambia, Namibia, Botswana and Zimbabwe. Records are very disjunct, but the gaps probably reflect insufficient collecting. Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Recorded from woodland savannas including *Isobertinia* woodland, *Acacia–Commiphora* bushland, miombo woodland and mopane woodland. Also recorded in mosaic of rainforest and secondary grassland. Often recorded near and over rivers, streams and pools.

Abundance Uncertain. Seldom collected and relatively uncommon in collections, but probably far more abundant than records indicate. Often the most commonly captured molossid over the Sengwa R. (Zimbabwe) during periods of low or no water (Jun, Oct, Nov) (Fenton & Eger 2002).

Adaptations Aspect ratio high; wing-loading low; wing-tip relatively broad; flight predictably moderately fast, agile and marginally more manoeuvrable than that of many molossids. By day, has been found in a horizontal crack in a branch in the crown of a tall mopane tree *Colophospermum mopane* and in a hole in a tree. The interaural crest of ♂♂ can be erected conspicuously or laid back almost out of sight (Lang & Chapin 1917b). The hairs of the crest resemble body hairs: i.e. they are not osmetrichia adapted for the dispersal of scent (Hickey & Fenton 1987). Apparently not known whether or not the crest arises from glandular tissue – possibly its main function is to provide visual cues but the circumstances eliciting erection of the crest are not known. *Tadarida chapini* has been recorded flying over water with *T. ansorgei* in NW Zimbabwe, and with *T. condylura*, *T. nigeriae*, *T. niveiventer* and *T. pumila* in W Zambia.

Foraging and Food Forages by fast-hawking in open spaces. Recorded over water, but not known if it forages over water or comes to drink, or both. Echolocation calls, including feeding-buzzes, assumed to have been emitted by *T. chapini*, have been recorded from 0 to 450 m above ground in Zimbabwe (Fenton & Griffin 1997). Analysis of faeces of 15 individuals collected in dry season in Zimbabwe contained mainly Coleoptera with some Lepidoptera, Diptera and other insects (Fenton & Thomas 1980).

Echolocation Search-phase call-shape: shallow FM (details not available). Start-frequency 27 kHz; end-frequency 19 kHz; maximum call-duration 10 ms (five bats; Fenton & Bell 1981).

Social and Reproductive Behaviour There are several records of an adult ♂ and ♀ being mist-netted together, suggesting that *T. chapini* possibly lives in pairs (Grubb *et al.* 1998), but this needs confirmation. Four pregnant ♀♀ were mist-netted together at dawn: when released in succession at dusk the next day, all four flew to one crack in a mopane tree (see above), suggesting that they roosted together. Not known if other individuals also used this day-roost.

Reproduction and Population Structure Litter-size: no information. Reproductive chronology uncertain. At ca. 15°S in W Zambia, 1 of 5 ♀♀ was pregnant at full term and four were lactating in early Nov (F. P. D. Cotterill unpubl.). At ca. 19°S (near Xugana, Botswana), 5 of 6 ♀♀ were lactating at beginning of wet season (6 Dec); no data for other months (Archer 1977). At ca. 18°S (Sengwa Wildlife Research Area, Zimbabwe), three ♀♀ were heavily pregnant and also lactating in mid-Jan, indicating polyoestrus with postpartum oestrus (F. P. D. Cotterill unpubl.). The data are consistent with seasonal polyoestrus, but the details are not yet known.

Predators, Parasites and Diseases Predators include Bat Hawks *Macheiramphus alcinus* (Allen 1917a). Ectoparasites: no information.

Conservation IUCN Category: Least Concern.

Tadarida condylura ANGOLAN FREE-TAILED BAT

Fr. Tadaride à queue libre; Ger. Angola-Bulldoggfledermaus

Tadarida condylura (A. Smith, 1833). S. Afr. Quart. J. 1: 54. Durban, KwaZulu–Natal, South Africa.

Taxonomy Originally *Nyctinomus condylurus*. Subgenus *Mops*. Synonyms: *angolensis*, *fulva*, *occidentalis*, *orientis*, *osborni*, *wonderi*. Often includes *leucostigma*, but Peterson *et al.* (1995) and Goodman (2011) consider this Madagascan form to be a distinct species. Subspecies: four (excluding *leucostigma*). Chromosome number (Uganda): $2n = 48$; $aFN = 56$ (Dulić & Mutere 1973b). In Somalia and South Africa, $2n = 48$; $aFN = 66$; one pair large metacentric, three pairs small metacentric, four pairs medium subtelocentric, two pairs small subtelocentric and 13 pairs medium-small acrocentric autosomes (Smith *et al.* 1986, Rautenbach *et al.* 1993).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears joined by interaural band; M^3 with third ridge present but $<$ half length of second ridge; anterior palatal emargination closed; wings pale greyish-brown; ventral pelage greyish-brown to whitish, ventral flank-stripe white; crown not darker than back; first phalanx of third and fourth finger comparatively long (cf. *T. demonstrator*, *T. niveiventer*). Sexes almost similar. Pelage short (mid-dorsal hairs 4–5 mm), sparse; covering rump but not extending onto interfemoral membrane; nape almost naked. Dorsal pelage blackish-brown, greyish-brown, pale grey or pale greyish-brown, sometimes with white flecks; hairs pale at base. Crown same colour as rest of dorsal pelage (cf. *T. niveiventer*). Ventral pelage greyish-brown, pale fawn, yellowish-white or whitish; mid-ventral markings white, varied in shape, sometimes absent; ventral flank-stripe white. The full range of dorsal and ventral colours can be found in a single colony. Neonates with dark skin (cf. *T. niveiventer*) (F. P. D. Cotterill pers. comm.). Head not extremely flattened. Upper lip with ca. seven well-defined wrinkles and many spoon-hairs. Ears blackish-brown; relatively short (reaching ca. half-way along muzzle when laid forward); inner margins joined by interaural band with backward-opening pocket-like invagination in middle. Tragus small, squarish, concealed by antitragus. Antitragus large, subrectangular with upper side convex with rounded corners, and thick. Males and ♀♀ with interaural crest of short, brown feathery hairs (osmetrichia) arising from the interaural pocket (Hickey & Fenton 1987). No gular gland. Wings semi-translucent, greyish-brown near body becoming paler towards tip. First phalanx of third finger 22.0 (20–24) mm, $n = 31$; first phalanx of fourth finger 18.3 (17–20) mm, $n = 21$ (cf. *T. niveiventer*, *T. demonstrator*). Interfemoral membrane dark greyish-brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase usually elevated slightly above plane of rostrum. Sagittal crest usually well developed; lambdoid crest usually very well developed; occipital helmet present, usually prominent, sometimes poorly developed. Anterior palatal emargination closed; incisive foramina visible. Basisphenoid pits shallow and often indistinct, small, their width ca. half their distance apart. Anterior upper premolar absent or distinctly shorter than cingulum of posterior premolar and usually displaced labially but sometimes within toothrow; canine

and posterior premolar in contact or nearly so. M^3 with third ridge present but variable in length – usually just a little less than half the length of second ridge but sometimes equal to, and sometimes much less than, half the length of the second. Two lower incisors on each side, bicuspid, crowded. Lower canines relatively short with cingula sometimes well separated, sometimes somewhat enlarged and almost in contact. Dental formula: $^{1123}/_{2123} = 30$ or $^{1113}/_{2123} = 28$.

Geographic Variation Four African subspecies are recognized by Koopman (1994), but not all populations are allocated to subspecies:

T. c. wonderi: Mauritania and Guinea-Bissau at least to Mali.

T. c. orientis: Tanzania.

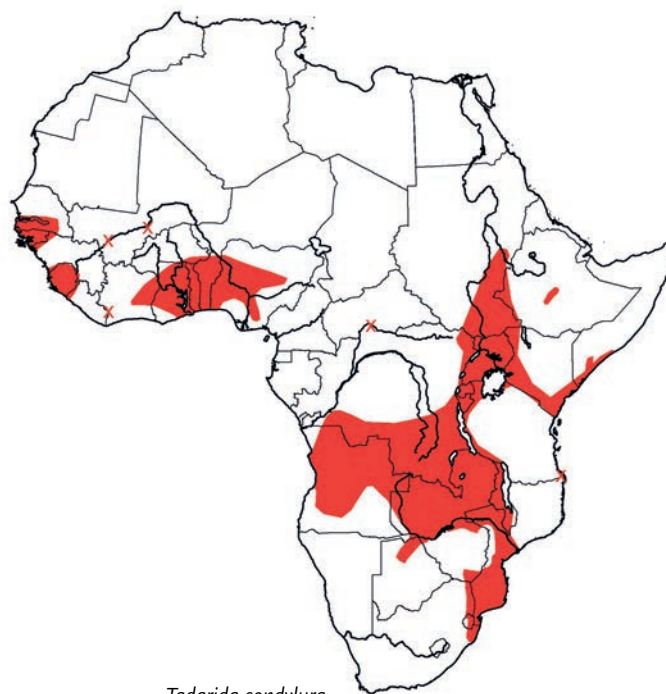

T. c. osborni: Congo and SW DR Congo.

T. c. condylura: Angola and SE DR Congo to Natal.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge present (but $<$ half length of second ridge) or absent; anterior palatal emargination closed; FA: >40 mm (Table 20, p. 488):

Tadarida niveiventer. Ventral pelage mostly white or cream; ventral flank-stripe same colour. Crown and neck darker than back. First phalanx of fourth finger almost always shorter (15.4 [15–17] mm). Skull with sagittal crest only moderately developed. Basisphenoid pits moderate in depth, medium-sized. M^3 with third ridge absent.

T. demonstrator. First phalanx of third finger shorter (17.7 [16–19] mm). Males with pair of glands between penis and anus.

Tadarida condylura

Ventral pelage white or very pale. Crown usually black, always darker than back. Tibia usually shorter (15–16 mm). Skull with sagittal crest weakly developed, basisphenoid pits deep. Dentition more robust; M^3 with third ridge absent.

T. congica. Larger and heavier (FA: 54–58 mm; WT: 42–64 g).

T. midas. Much larger and heavier (FA: 59–67 mm; WT: 38–69 g).

T. trevori. Forearm almost always longer (51–55 mm). Wings dark brown. No ventral flank-stripe in contrasting colour. Skull with basisphenoid pits deep and large.

Distribution Endemic to Africa. Very widespread south of the Sahara. Mainly recorded from the Sudan Savanna, Guinea Savanna and Coastal Forest Mosaic BZs, the Rainforest–Savanna Mosaic, and the Zambezi Woodland BZ from Senegal to Somalia and south to Angola, Botswana and KwaZulu–Natal (South Africa). Also recorded from some parts of the Rainforest BZ in the Western Region, but not from any other region. Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Recorded mainly in woodland savannas including undifferentiated woodlands, *Isobertia* woodland, mosaics of rainforest and secondary grassland, wetter and drier miombo woodlands, coastal mosaics, *Acacia–Commiphora* bushland and thicket, and other thicket bushlands. Not recorded in undisturbed rainforest habitats, montane areas (except possibly in Ethiopia) and arid areas (except near large rivers in S Somalia). Not dependent on rocky, hilly or mountainous terrain for its roosts.

Abundance Common.

Adaptations Aspect ratio high; wing-loading high to very high. Flight fast, agile with very poor manoeuvrability; turns by banking (radius of turn >1.5 m) but not by stalling-and-twisting; cannot hover or take off from ground; must dive to gain sufficient speed for flight, and swoops upwards to reduce speed prior to landing. Unable to fly in a 1×1×1 m enclosure (M. Happold unpubl.). Scuttling and climbing are fast and efficient. Often roosts by day, clinging or crouching, under corrugated iron roofs; also roosts in nooks and crannies within hollow trees and palms, caves, mines and in the fabric of various buildings. Under roofs, microclimatic temperatures and relative humidities vary daily and seasonally, and reach challenging extremes: 17–39°C and 39–94% in Uganda (Mutere 1969), >40°C during summer days to <10°C during winter nights in South Africa (Bronner *et al.* 1999). Individuals under hot roofs often move from place to place as temperatures change. If possible, they choose 35–42°C (and 30–40%), presumably to minimize cost of thermoregulation without compromising reproductive activity or the ability to avoid predators (Bronner *et al.* 1999). Can survive at 40°C for 11 hours; panting and localized sweating (but not wing-fanning) sometimes occur after prolonged exposure to high temperatures. Becomes torpid at temperatures below thermal neutrality. Sometimes shares roosts with *T. pumila*. Because it is necessary to dive to gain flight speed, entrances are always at least 1.5 m above ground; landing-sites are often stained; individuals often scuttle several metres from landing-sites to roost-sites. Large colonies have a pungent smell (to humans), are noisy and produce much guano; therefore *T. condylura* is often regarded as

a pest. Starts emerging 15–60 min after sunset; time not correlated with season or weather. In Swaziland, sometimes does not emerge on cold wet nights (Monadjem 1998a). Predicted mean maximum urine concentration is comparatively very low (2634 mOsmol/kg). Despite this, non-flying captive bats, even when pregnant, did not drink, but independence of drinking water in the wild is very unlikely because of the high evaporative water loss from the wings during flight (Happold & Happold 1988). The ability of *T. condylura* to utilize thermo-challenging roosts reflects, in part, its tolerance of dehydration rather than its ability to maintain water balance (Buffenstein *et al.* 1999).

Foraging and Food Forages by fast-hawking in open spaces above tree canopies, over clearings and open water, and along fairly open waterways. Often seen foraging between 10–100 m above ground, but also as low as 2–3 m above open ground. Combines circling (sometimes gaining height) with long, straight flights; swerves and dives in pursuit of prey. Often forages in twos, the following bat flying lower than the leader, perhaps to catch moths that close their wings and fall, in response to the echolocation calls of the leader (M. Happold unpubl.). Captive bats foraged while scuttling around their cages/enclosures, and faeces of wild bats contained cockroaches (not necessarily flightless species), which were abundant in their day-roosts: this suggests that opportunistic foraging by chasing occurs in the day-roosts. Feeds opportunistically on very hard-shelled beetles as well as soft-bodied insects. Sometimes feeds mainly on beetles but also takes Hemiptera, Lepidoptera, Odonata, Homoptera and other insects (Verschuren 1957, Whitaker & Mumford 1978).

Echolocation Search-phase calls (Malawi) are mostly shallow linear FM or shallow sigmoid FM sweeps of very narrow bandwidth; end-frequency variable (18–30 kHz); call-duration 5–15 ms. About 7–30% of the calls are shallow linear FM sweeps (cf. 90–100% in *T. pumila*) with end-frequencies 21–24 kHz, bandwidths from 1 to 4 kHz and durations of 5–15 ms (eight light-tagged bats foraging, one flying high after release; M. Happold unpubl.). Individuals often insert a single, shallow linear FM or shallow quasi-linear FM call, with very narrow bandwidth and relatively low start- and end-frequencies, between sequences of 1–3 calls with wider bandwidths and higher start- and end-frequencies (Figure 113). This distinct alternation can be heard with a bat-detector (M. Happold unpubl.). Alternation between calls of different frequencies has been recorded

Figure 113. Sonograms of a sequence of search-phase echolocation calls with alternating broad bandwidth and narrow bandwidth calls, emitted by one *Tadarida condylura* while foraging in open space high above the ground (M. Happold unpubl.).

in the non-African molossid *Cheiromeles torquatus*, but not, as yet, for other African species. In cluttered environments (near day-roosts and/or the ground), and also when flying with flocks of conspecifics, *T. condylura* emits steep linear and steep quasi-linear FM sweeps with start-frequencies 28–50 kHz and end-frequencies 18–34 kHz. As individuals fly from cluttered to open spaces, their calls change gradually from broad to narrow bandwidth, and vice versa when approaching prey or returning to cluttered environments.

Social and Reproductive Behaviour Forages singly, in twos or in large groups. Roosts in groups of 10–20 in small natural day-roosts, but in groups of several hundred in buildings. Huddles, sometimes three deep, with much jostling, climbing-over, pushing-under, twittering and squeaking prior to settling down. There is also much movement and vocalizing for 1–2 hours prior to emergence. A colony in Malawi was noisiest in Oct: no apparent correlation between noise level and reproductive state. Composition of colonies and social organization not yet known. The ratio of ♂♂ to ♀♀ in a colony of 369 in Uganda was 1 : 0.7 (Mutere 1969). Mutere found that ♂♂ emerged earlier than ♀♀, which explains why samples of emerging bats taken soon after sunset often contain more ♂♂ than ♀♀. Verschuren (1957) suggested temporary segregation of sexes might occur, but no evidence of sexual segregation has been reported in other studies. On two occasions, in Mar and Jun in Malawi, several hundreds of *T. condylura* were seen flying anticlockwise in a circle 100–200 m in diameter, 10–15 m above ground over open ground near their day-roost. This flight was sustained for more than two hours; its significance is not known (Happold *et al.* 1987).

Reproduction and Population Structure Litter-size: one. Right ovary dominant; implantation in right uterine horn. Reproductive chronology apparently seasonal bimodal polyoestry throughout geographic range, but the interval between consecutive births decreases with increasing latitude so that births coincide with peaks in rainfall. At 0–1° N in Uganda, births occurred in Feb–Mar and Jul–Aug, just before each peak in rainfall (Mutere 1973a). At 02° 18' S (Masalani, inland Kenya), births occur in each of the two wet seasons (Nov, and Mar–Apr) (O'Shea & Vaughan 1980). At 14–16° S in Malawi, births occur in Nov–Dec and Feb–Mar; there is a postpartum oestrus and gestation is ca. 90 days (Happold & Happold 1989b). At 24–26° S (former eastern Transvaal, South Africa), births occur in mid-Dec and early Apr; there is a postpartum oestrus and conception within 18 days of first birth; gestation 85 days, lactation 50–60 days; reproductive quiescence May–Aug (Vivier & van der

Merwe 1997). In ♂♂, spermatogenic activity peaks in Aug to early Sep and Nov to early Dec (Vivier & van der Merwe 1996).

Predators, Parasites and Diseases Individuals scuttling over a roof prior to taking off from its edge were taken by a Central African Large-spotted Genet *Genetta maculata* in Malawi. Often taken by Bat Hawks *Macheiramphus alcinus*, and sometimes by other raptors, as the bats dive away from their day-roosts. Ectoparasites include a bed-bug *Loxapsis miranda* (Hemiptera: Cimicidae); fleas *Lagaropsylla consularis*, *L. duodecima*, *L. incerta*, *L. idae*, *L. leleupi*, *L. obliqua* (Siphonaptera: Ischnopsyllidae); a bat-fly *Nycteribia schmidli* (Diptera: Nycteribiidae); a tick *Lepidixodes kopsteini* (Acari: Ixodidae); and nine species of mites (Acari: Spinturnicidae, Macronyssidae, Trombiculidae, Chirodiscidae, Sarcoptidae) (Anciaux de Faveaux 1984, Beaucournu & Kock 1996). Viruses isolated from *T. condylura* include Bunyamwera, Yellow Fever, Chikungunya, West Nile and Zika, which can cause illness in humans, and Bukalasa Bat, Dakar Bat and Entebbe Bat viruses, which are not known to cause illness in humans (Metselaar *et al.* 1966, Anciaux de Faveaux 1984, C. Calisher pers. comm.).

Conservation IUCN Category: Least Concern.

Well adapted to semi-urban and agricultural areas.

Meredith Happold

Tadarida congica CONGO FREE-TAILED BAT

Fr. Tadaride du Congo; Ger. Kongo-Bulldoggfledermaus

Tadarida congica (J. A. Allen, 1917). Amer. Mus. Nat. Hist. 37: 467. Medje, Orientale, NE DR Congo.

Taxonomy Originally *Mops congicus*. Subgenus *Mops*. Synonyms: none. Does not include *T. trevori*, which was considered a subspecies of *T. congica* by Koopman (1965) and Hayman & Hill (1971) but subsequently shown to be a distinct species (Peterson 1972, Freeman 1981). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid (FA: 54–58 mm; WT: 42–66 g); ears joined by interaural band; M³ with third ridge absent or weakly developed; anterior palatal emargination closed; wings blackish-brown; ventral pelage variable but not white or

whitish, no ventral flank-stripe in contrasting colour; dorsal pelage dark brown to almost black; crown not darker than back. Males on average larger than ♀♀ in skull dimensions. Pelage short, moderately sparse on nape; flanks and posterior of rump naked. Dorsal pelage dark brown to almost black, often with isolated, pale hairs but no spots or flecking; hairs medium brown with dark brown or black at tip. There is a pronounced and well-defined dark patch behind and below the ear (cf. smaller and poorly defined in *T. trevori*). Ventral pelage variable, with a strong wash of grey, brown or rusty colour, resulting in a mottled appearance; no mid-ventral markings; ventral flank-stripe same colour as flanks. Head not extremely flattened. Upper lip with 7–8 well-defined wrinkles on each side and many spoon-hairs. Ears blackish, thick and leathery; not reaching snout when laid forward. Inner margins of ears joined across forehead by a thick interaural band with strong cartilaginous pocket-like support. Tragus minute, concealed by antitragus. Antitragus large, rounded dorsally with a rather straight anterior edge. Interaural crest: no information. No gular gland. Wings blackish-brown. Third metacarpal: 53–60 mm, $n = 38$; fourth metacarpal: 51–58 mm, $n = 28$ (cf. *T. trevori*).

Skull large and robust, not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum. Sagittal crest comparatively well developed anteriorly, lower posteriorly. Lambdoid crest moderate to well developed. Anterior palatal emargination closed. Basisphenoid pits deep, large, their width greater than their distance apart. Anterior upper premolar usually lower than cingulum of posterior premolar, within toothrow; canine and posterior upper premolar separated. M^3 with third ridge absent or weakly developed. Upper and lower canines in ♂♂ much larger than in ♀♀. Two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged and not in contact. Dental formula: $1^{123}/_{2123} = 30$.

Geographic Variation None recorded, but data are limited.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge present (but usually* < half length of second ridge) or absent; anterior palatal emargination closed; FA: >40 mm (Table 20, p. 488). *In *T. condylura*, the length of the third ridge is variable and can be up to half length of second ridge.

Tadarida midas. Forearm longer (59–67 mm). Pelage more variable and generally paler, usually greyish, with frosted appearance and some whitish flecking. Skull of similar length but more robust and often wider (GWS: 15.2–18.1 mm).

T. trevori. FA usually shorter (51–55 mm), third and fourth metacarpals usually shorter (see Description). Dorsal pelage not dark brown to almost black. Interaural band much thinner. Skull usually smaller (GLS: 23.1–25.1 mm).

T. condylura. Smaller and lighter (FA: 45–51 mm; WT: 16–39 g).

T. niveiventer. Smaller and lighter (FA: 44–48 mm; WT: 20–30 g).

Ventral pelage mostly white or cream.

T. demonstrator. Much smaller and lighter (FA: 41–46 mm; WT: 20–24 g).

Distribution Endemic to Africa. Recorded in Rainforest BZ (West Central and East Central Regions) and marginally in Northern and

Tadarida congica

Eastern Rainforest–Savanna Mosaics. Known from seven localities in Cameroon, DR Congo and Uganda (Peterson 1972, Freeman 1981, Breman *et al.* 1999, RMCA, USNM). Records from Pampramase, Ghana (Jeffrey 1975) and Agege, Nigeria (Bergmans 1977b) are referable to *T. trevori* (Fahr *et al.* 2006). Based on habitat, a record from Guinea savanna in Bamingui-Bangoran N. P., Central African Republic (Spinage 1988) might also represent *T. trevori* but specimens need checking. An unspecified record for Gambia by Koopman (1993) is erroneous and probably refers to *T. demonstrator*, which is listed for Senegambia & Mauritania by Koopman *et al.* (1995); see also Koopman (1989).

Habitat Recorded from lowland rainforest, coastal forest and rainforest–savanna mosaic vegetation zones. Seems to be more closely associated with rainforest than its sister species, *T. trevori*, which is mainly found in the forest–savanna mosaic and woodland savannas north and east of the Rainforest BZ.

Abundance Appears to be very rare and localized, but this might reflect insufficient sampling, in suitable habitat, using elevated mist-nets.

Remarks One ♂ and 12 ♀♀ (the type series) roosted by day in the hollow trunk of a tree, and were captured when the tree was felled by a violent storm; this roost was shared by a colony of *T. russata* (see profile) (Lang & Chapin 1917b). In W Uganda, Kingdon (1974) observed individuals foraging just before dark, and coming down to drink at 19:30h in early Mar; he shot and mist-netted a 'large series' of which 'almost all' of the adult ♀♀ were 'very recently pregnant'. Three subsequent efforts to collect, at different times of the year and in the same locality, did not reveal any other bats of this species. This, together with a record by Lang & Chapin (1917b) that five of 12 ♀♀ were pregnant (each with one large embryo) in Sep, 60 years earlier and 200 km to the north-west, led Kingdon (1974) to suggest that these bats have a 'biannual breeding season' and that

they may migrate or undergo seasonal movements, but all of these suggestions need confirmation. The host of the ectoparasite *Allopyssa alloides* (Siphonaptera: Ischnopsyllidae) was published as *T. congica* by Smit (1977) but is here re-identified as *T. trevori*.

Conservation IUCN Category: Near Threatened.

Based on its patchy distribution and tight association with forest, a decline can be expected in future. Major threats: loss and degradation of habitat caused by logging and agriculture. Population trend not known.

Jakob Fahr

Tadarida demonstrator MONGALLA FREE-TAILED BAT

Fr. Tadaride de Mongalla; Ger. Mongalla-Bulldogfledermaus

Tadarida demonstrator (Thomas, 1903). Ann. Mag. Nat. Hist., ser. 7, 12: 504. Mangala [= Mongalla], Bahr el Jebel, Equatoria Prov., S Sudan.

Taxonomy Originally *Nyctinomus demonstrator*. Subgenus *Mops*. Synonyms: *faradjius*. Subspecies: none currently recognized. Koopman considered (1994) or discussed (1993) the possibility that *niveiventer* is a subspecies of *T. demonstrator*, but Freeman (1981) treated *niveiventer* as a separate species although most closely related to *T. demonstrator*. Chromosome number (Cameroon): 2n = 48; aFN = 54 (Smith *et al.* 1986).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid (FA: 41–46 mm); ears joined by interaural band; M³ with third ridge absent; anterior palatal emargination closed; wings medium to dark grey; ventral pelage white or very pale; no ventral flank-stripe in conspicuously contrasting colour; crown usually black, always darker than back; ♂♂ with paired glands near base of penis; first phalanges of third and fourth fingers comparatively short (cf. only *T. niveiventer*, *T. condylura*). Sexes almost similar. Pelage short (mid-dorsal hairs 2–5 mm), moderately sparse on nape. Dorsal pelage medium brown to slaty-grey, often suffused with pale grey or silvery-white giving frosted appearance; no distinct spots but slight to moderate flecking in some specimens; hairs white to pale grey with tip darker (greyish-brown to dark slaty-grey). Crown of head darker than back, usually black (as in *T. niveiventer*). Ventral pelage pure or creamy white to very pale grey; darker towards the flanks; hairs unicoloured; no mid-ventral markings; ventral flank-stripe whitish or pale grey, paler than flanks but not contrasting with mid-ventral colour. Head not extremely flattened; muzzle comparatively short, rounded and sturdy. Upper lip with 7–8 well-defined wrinkles on each side; very few spoon-hairs. Ears dark grey, relatively short (not reaching muzzle when laid forward); inner margins joined across forehead by a relatively

low interaural band with a forward-pointing, V-shaped fold in middle or forward-pointing, pocket-like invagination in middle. Tragus minute, concealed by antitragus. Antitragus large, rounded above with broad base. Posterior side of interaural band supporting longer and stronger black hairs, but not a distinct interaural crest. No gular gland. Wings medium to dark grey. First phalanx of third finger 17.7 (16–19) mm, n = 15; first phalanx of fourth finger 14.2 (13–16) mm, n = 15. Males with paired glands near base of penis, opening towards tail.

Skull large and robust relative to the size of the bat; not extremely dorsoventrally flattened. Anterior of braincase not noticeably rising above plane of rostrum. Sagittal crest well developed to weakly developed anteriorly, weakly developed posteriorly; lambdoid crests moderately developed, usually forming a weakly-developed helmet in older individuals, especially ♂♂. Anterior palatal emargination closed; incisive foramina present. Basisphenoid pits deep, large, their width > their distance apart. Anterior upper premolar distinctly shorter than cingulum of posterior premolar and usually displaced labially, sometimes absent; canine and posterior upper premolar in contact or almost so. M³ with third ridge absent. Two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged, separated by narrow gap. Dental formula: $\frac{1^{123}}{2_{123}} = 30$.

Geographic Variation Apparently none.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge present (but usually* < half length of second ridge) or absent; anterior palatal emargination closed; FA: >40 mm (Table 20, p. 488). *In *T. condylura*, the length of the third ridge is variable and can be up to half length of second ridge.

*Tadarida demonstrator*

Tadarida condylura. First phalanx of third finger longer 22.0 (20–24) mm. Males without scent-glands between penis and anus. Ventral pelage often with little or no white. Crown and neck same colour as back. Tibia usually longer (16–20 mm). Skull with sagittal crest usually well developed; basisphenoid pits shallow. Dentition less robust; M^3 with third ridge present (usually half to < half length of second ridge).

T. niveiventer. First phalanx of third finger almost always longer (19.4 [19–21] mm). Males without scent-glands between penis and anus. Wings pale grey. Basisphenoid pits moderate.

T. trevori. Larger (FA: 51–55 mm). Males without scent-glands between penis and anus. Dorsal pelage not frosted.

T. congica. Much larger and heavier (FA: 54–58 mm; WT: 42–64 g).

T. midas. Much larger and heavier (FA: 59–67 mm; WT: 38–69 g).

Distribution Endemic to Africa. Recorded from Sahel Savanna (but only in Blue Nile Valley), Sudan Savanna and Guinea Savanna BZs and the Northern and Eastern Rainforest–Savanna Mosaics. Known from 26 localities in N Côte d'Ivoire (Comoé N. P., Mt Sangbé N. P.; J. Fahr unpubl.), Burkina, Ghana, N Cameroon, Sudan, NE DR Congo and NW Uganda. A record from Kwabenya (Legon, Ghana) by Koopman *et al.* (1995) and cited by Grubb *et al.* (1998) does not represent *T. demonstrator*. A BMNH specimen taken 'at sea off Gambia' and mentioned by Koopman (1989) is disregarded by Grubb *et al.* (1998).

Habitat Prefers relatively open and dry savanna vegetation zones (such as *Isobelinia* woodland) as well as forest–savanna mosaic but, based on the known records, it seems that the distribution of this bat often follows larger rivers, especially in the north-eastern and drier parts of its geographic range. In Sudan, found along the Blue Nile R. where it runs through Sahel *Acacia* wooded grassland, and along the White Nile R. where it flows through *Acacia* wooded grassland and also through the Sudd with its seasonally flooded grasslands and semi-aquatic vegetation.

Abundance Uncertain. Appears to be localized and comparatively rare, but this might reflect insufficient sampling in suitable habitat using elevated mist-nets.

Adaptations In Garamba N. P., NE DR Congo, found roosting only in natural roosts, usually 3–4 m above ground: these included under bark, and in very narrow fissures and cracks in the trunks or branches of trees including *Terminalia*, *Vitex doniana* and *Parinari* sp. (Verschuren 1957, as *faradjius*). One roost was located in the same tree in which an owl had its nest with a young. In Garamba N. P., both *T. condylura* and *T. midas* roosted in the same sorts of places, but *T. demonstrator* was seldom found roosting with these molossids; on one occasion only, a group was found roosting with two *T. midas* and one *Nycticeinops schlieffeni* (Verschuren 1957). Unlike *T. condylura*, not found roosting under the roofs of houses in this locality. In Sudan, however, one individual was caught (together with 12 *T. pumila*) as it emerged from the thatch of a house (Kock 1969a).

Foraging and Food Forages by fast-hawking, high above the ground and vegetation. In Comoé N. P., Côte d'Ivoire, in mist-nets set 0–25 m above ground, captured at median height of 16.4 (8.4–19.6) m, $n = 4$ (J. Fahr unpubl.). In W Uganda, Kingdon (1974) mist-netted this bat early in the evening. Diet not known but likely to consist of comparatively hard-shelled, flying insects.

Social and Reproductive Behaviour In Garamba N. P., both ♂♂ and ♀♀ were found roosting singly or in small groups comprised of 2–10 individuals (Verschuren 1957). The groups included all-female groups of 2–7 ♀♀, and groups containing at least one ♂ with at least two ♀♀ (but sexes of some group-members not determined). One group included three ♂♂ and two ♀♀ and four others not sexed. In a collection of 35 sexed bats taken from 11 day-roosts occupied by a total of 42 bats, the ratio of ♂♂ to ♀♀ was 1 : 4.8. According to Verschuren (1957) this sex ratio reflects the social structure in the day-roosts (1 ♂ to ca. 5 ♀♀), but the group-compositions (which he tabulated) show that the compositions of groups are actually very variable. Verschuren (1957) also suggested that perhaps ♀♀ roost separately from ♂♂ during the parturition season, but this needs confirmation.

Reproduction and Population Structure Litter-size: not known (probably one). Reproductive chronology not known. At 03°55'N (Garamba N. P., NE DR Congo), pregnant ♀♀ (near term) were recorded in Apr and Jun, and one with a very small embryo in Sep; one lactating ♀ in Jun; juveniles in May, Jun and Sep (no data given for other months) (Verschuren 1957, as *faradjius*). In one all-female colony, 4 of 5 adults were pregnant (near term) and the other lactating, suggesting synchrony at least between ♀♀ roosting together. The data suggest polyoestry (as in several other African molossids), but this needs confirmation.

Predators, Parasites and Diseases The holotype of *faradjius* was taken from the crop of an African Bat Hawk *Macheiramphus alcinus* at Faradje, DR Congo, together with *Tadarida chapini*, *Pipistrellus nanus* and *P. tenuipinnis* (Lang & Chapin 1917b). Ectoparasites include a flea *Lagaropsylla hoogstraali* (Siphonaptera: Ischnopsyllidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Major threats: destruction of roost sites (mature trees) in savanna habitats, loss and degradation of habitat especially as result of wood extraction including selective logging. Population trend inferred to be declining.

Tadarida fulminans MADAGASCAN FREE-TAILED BAT (MALAGASY FREE-TAILED BAT)

Fr. Tadaride de Thomas; Ger. Madagassische Bulldoggfledermaus

Tadarida fulminans (Thomas, 1903). Ann. Mag. Nat. Hist., ser. 7, 12: 501. Fianarantsoa, eastern Betsileo, Madagascar.

Taxonomy Originally *Nyctinomus fulminans*. Subgenus *Tadarida*. Synonyms: *mastersoni*. Subspecies: two. Chromosome number (South Africa): 2n = 48; aFN = 66. X = medium metacentric, Y = small acrocentric (Rautenbach *et al.* 1993).

Description Medium-small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; large for an African molossid; ears relatively short, meeting to form a V-shaped valley; wings brown dorsally, whitish ventrally; ventral flank-stripe white, cream or yellowish; two lower incisors on each side; M³ with third ridge > half length of second ridge. Sexes different in colour, similar in size. Pelage velvety; mid-dorsal hairs 6–7 mm. Dorsal pelage (♀ ♀) dark chocolate brown; no spots or flecking; hairs pale greyish-brown with dark chocolate brown tips. Ventral pelage (♀ ♀) dark chocolate brown on flanks, paler on abdomen with white or cream mid-ventral band; ventral flank-stripe white or cream. Dorsal pelage (adult ♂ ♂) reddish-brown; no spots or flecking; hairs with basal half pale greyish-brown or creamy-fawn. Ventral pelage (adult ♂ ♂) reddish-brown on flanks, paler on abdomen with cream or yellowish mid-ventral band; ventral flank-stripe yellowish. Subadults same as adult ♀ ♀. Head not extremely flattened. Upper lip without well-defined wrinkles; comparatively few spoon-hairs. Ears dark brown, comparatively small (not reaching snout when laid forward); with inner margins meeting at base of forehead to form a V-shaped valley. Tragus large, roughly rectangular, not concealed by antitragus. Antitragus low, triangular, only slightly larger than tragus. No interaural crest. Gular gland naked, conspicuous especially in ♂ ♂ in which it is often ringed by greenish hairs. Wing-membranes brown dorsally (paler over phalanges), whitish ventrally becoming browner towards tips. Interfemoral membrane dorsally brown, ventrally whitish, darkening towards margins. Ventral sides of forearms and legs naked and white. Foot with raised pad on sole (plantar pad).

Skull not extremely dorsoventrally flattened. Anterior of braincase elevated above plane of rostrum, but sometimes only slightly. Sagittal crest very weakly developed in ♂ ♂, absent in ♀ ♀; lambdoid crests

well developed in both sexes. Anterior palatal emargination wide. Interdental palate broad posteriorly, narrowing smoothly towards canines with only a slight constriction at level of posterior premolars (cf. *T. lobata*). Basisphenoid pits deep, large, their width greater than their distance apart. Upper incisors short and close together. Anterior upper premolar ca. same height as cingulum of posterior premolar, slightly displaced labially but canine and posterior premolar not in contact although sometimes nearly so. M³ with third ridge > half second ridge. Two lower incisors on each side, bicuspid and crowded. Lower canines well developed; cingula not greatly enlarged but nearly in contact. Dental formula: $\frac{1123}{2123} = 30$.

Geographic Variation None recorded.

Similar Species Four other *Tadarida* in Africa have ears with inner margins meeting, or almost meeting, to form a V-shaped valley:

Tadarida aegyptiaca. Almost always smaller (FA: 42–55 mm; GLS: 17.1–21.9 mm). Wings brown or blackish ventrally and dorsally. Ventral pelage with no mid-ventral markings and usually no ventral flank-stripe in contrasting colour.

T. lobata. Inner margins of ears meeting close to snout; ears extending well beyond snout when laid forward. White spot between shoulder-blades of adults. Skull with interorbital constriction slight; interdental palate markedly constricted at level of posterior premolar. Lower canines with cingula separated by the incisors.

T. teniotis. Three lower incisors on each side. Wings blackish. North Africa.

T. ventralis. No ventral flank-stripe in contrasting colour. Foot usually without plantar pad. Skull usually larger and more robust (GLS: 23.4–26.1 mm). Upper incisor longer.

Distribution In Africa, recorded mainly from Somalia–Masai Bushland, Zambezian Woodland and Afromontane–Afroalpine BZs, but probably extends into Eastern Rainforest–Savanna Mosaic near mountainous areas. Recorded from E DR Congo, Uganda, Rwanda, Kenya and Tanzania and southwards to NE South Africa

(Harrison 1971, Hayman & Hill 1971, Ansell 1978, Baeten *et al.* 1984, Happold *et al.* 1987, Cotterill 1996b, 2001c). Extraliminally: Madagascar (two specimens – the holotype collected in late nineteenth century and a melanistic topotype [FMNH 166074] collected in 1999).

Habitat Apparently prefers woodland savannas where steep rocky terrain provides suitable day-roosts. No details for the northern records except many appear to be near mountains. In Malawi, recorded in miombo woodland at base of Mulanje Mountain, which is a great, granite-syenite massif with precipitous, bare sides. In SW Zambia and NW Zimbabwe, recorded from the precipitous basalt gorges of the Upper Zambezi R. (Victoria Falls and Kalomo). In S and E Zimbabwe, recorded from a range of habitats including miombo and mopane woodlands, but mostly recorded in miombo woodland on the granitic shield, especially in rugged granite country where there are high, steep-sided inselbergs (Cotterill 2001c). Also recorded from day-roosts in a dolomite cave and in Karoo sandstone in the Sebungwe and Limpopo basins.

Abundance Locally common, but patchily distributed (based on a series collected in Rwanda, and observations and captures at roosts in NE and S Zimbabwe). Distribution and abundance is probably determined by the availability of suitable day-roosts (Cotterill 2001c). Rarely collected because it flies high and roosts in inaccessible places.

Adaptations Aspect ratio very high; wing-loading very high to exceptionally high (F. P. D. Cotterill unpubl.); this species, and *T. ventralis*, have the narrowest wing-tips found in any African *Tadarida* (Freeman 1981). Flight fast, agile, usually direct (Smithers 1983); manoeuvrability very poor; the agile swooping flight as a bat returns to its day-roost, with air rushing over its wings, is very reminiscent of the flight of swifts (Apodidae). Adept at rapid scuttling forwards,

backwards and sideways. Cannot take off from ground, and needs to dive to gain sufficient speed for flight. Roosts by day in narrow, horizontal rock-crevices located either high up in vertical cliffs or under overhangings. In Zimbabwe, most known roosts are in granite inselbergs; one colony roosted in cracks in the ceiling of a dolomite cave. Scuttles around roost-sites; scuttles backwards into crevices, using tip of tail to feel the way. In Zimbabwe, sometimes shares roosts with *T. ansorgei* and *T. bivittata* (Cotterill & Fergusson 1993a). Often mist-netted over water, suggesting dependence on accessible water for drinking.

Foraging and Food Forages by fast-hawking. Emerges at dusk, remains active all night and does not return to the day-roost until just before first light (Smithers 1983, F. P. D. Cotterill pers. obs.). Feeds on flying insects; details not known.

Echolocation Search-phase call-shape shallow FM. In Zimbabwe, start-frequency 27 kHz; end-frequency 14 kHz; peak-frequency 17 kHz; maximum duration 20 ms (1 bat, flying free; Fenton & Bell 1981). In South Africa, start frequency 27 kHz; end-frequency 14 kHz; intensity high (one bat in flight-cage; Aldridge & Rautenbach 1987).

Social and Reproductive Behaviour Roosts singly or in groups. No more than 20 individuals have been taken from any one day-roost but, in some cases, not all group-members were taken (Smithers 1983, F. P. D. Cotterill pers. obs.). Four captive adult ♂♂ roosted separately, suggesting that they are territorial; adult ♂♂ have also been observed roosting singly in rock-crevices. In contrast, captive ♀♀ huddled tightly together (F. P. D. Cotterill & N. C. Bennett unpubl.). Within day-roosts, there is much jostling and squeaking (audible to humans). Group-members emerge from the roost together, and make shrill squeaks as they dive away.

Reproduction and Population Structure Litter-size: one ($n = 10$); only right ovary is functional. Based on small samples of ♀♀ collected at 17° 30'S in NE Zimbabwe at ca. monthly intervals from Jul 1988 to Sep 1989 (Cotterill & Fergusson 1993b), the reproductive chronology appears to be seasonal polyoestrus, but further data are needed to elucidate the details. Births followed by postpartum oestrus are inferred to have occurred in ca. Mar–May at beginning of dry season (evidence: in late Jul, 3 of 5 ♀♀ were simultaneously lactating and in very early pregnancy and two were lactating with sperm *in uteri* and *in vaginae*; and in late Aug, 4 of 4 ♀♀ were post-lactating and in early pregnancy). In mid-Oct, 3 of 3 ♀♀ were pregnant. In mid-Nov, 5 of 5 ♀♀ were lactating and also pregnant with full-term foetuses; this indicates births from ca. late Oct to Nov (beginning of hot-wet season) and suggests either that the lactation period after the Mar–May births is exceptionally long, or that these bats had had a previous litter in ca. Aug at some other locality. There was no evidence of postpartum oestrus after the Oct–Nov births (8 of 8 ♀♀ in Dec, 5 of 5 in Feb and 2 of 2 in Apr were lactating but not pregnant), therefore this study did not indicate when the ♀♀ that gave birth in Mar–May became pregnant. Perhaps only some ♀♀ have a postpartum oestrus following births in Oct–Nov, or perhaps births in May–Jun do not occur every year. Perhaps this species migrates, and

its reproductive chronology cannot be elucidated from studies at only one locality. Considered overall, the unusual reproductive chronology of *T. fulminans* suggests that the pattern of annual fluctuation in the availability of its prey differs from those of the prey exploited by other Chiroptera.

Predators, Parasites and Diseases Predators include Mackinder's Eagle-owl *Bubo capensis*, which has been observed capturing this bat in NE Zimbabwe (Cotterill 1992). Ectoparasites include a bed-bug *Crassimex sexualis* (Hemiptera: Cimicidae), another bug *Hypoctenes faini* (Hemiptera: Polycetidae) and mites *Microtrombicula intranasalis* (Acari: Trombiculidae), *Notoedres* spp. (Acari: Sarcopidae) (Anciaux de Faveaux 1984). All examined *T. fulminans* carried one or more interstitial nematodes (ca. 10 mm overall length), clearly visible under skin on underside of wing-membrane along anterior edge of the forearm. (Note: internal parasites are not mentioned in other profiles.)

Conservation IUCN Category: Least Concern.

Tadarida gallagheri GALLAGHER'S FREE-TAILED BAT

Fr. Tadaride de Gallagher; Ger. Gallaghers Bulldoggfledermaus

Tadarida gallagheri Harrison, 1975. Mammalia 39: 313. Scierie Forest, 30 km south-west of Kindu, DR Congo.

Taxonomy Currently in subgenus *Chaerephon*. Synonyms: none. At the time of its discovery, the uniqueness of this little molossid, especially its nasal swellings and interaural membrane morphology, suggested that it might represent a distinct genus (Harrison 1975). Subsequently, *T. tomensis*, another species with very similar nasal swellings and interaural membrane morphology, was described from São Tomé (Juste & Ibáñez 1993b). Both of these species bear some resemblance to *Tadarida* (*Chaerephon*) *johorensis* from Asia. Chromosome number: not known.

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid; with inner margins of ears joined by an interaural membrane and a large, bulbous, interaural lobe, which projects well forward over the muzzle and dominates the lateral profile of the head (Figure 97g): no other mainland species resembles this bat. Sexual dimorphism: no information (only one ♂ specimen known). Pelage short (mid-dorsal hairs 5–6 mm). Dorsal pelage uniformly umber brown; no spots or flecking. Ventral pelage uniformly umber brown; no mid-ventral markings; ventral flank-stripe umber brown. Head not extremely flattened; muzzle blunt with transverse ridge above snout. Upper lip with five well-defined wrinkles on each side and few spoon-hairs except in front of the snout. Ears relatively large, extending beyond snout when laid forward; inner margins joined by a naked interaural membrane that rises centrally to form a flat-topped, truncated triangle with convex sides. Below this, there is a large bulbous lobe, which projects forward over the muzzle

and extends beyond the snout. This lobe is penetrated by a deep, backward-opening pocket. The pocket is bordered by two vertical hairless folds of skin, which extend backwards out of the pocket and unite on the crown of the head. Arising from the smooth floor of the pocket is an interaural crest of dark brown hairs, ca. 9 mm long, and presumably the pocket can be partly everted to display this crest. Tragus small but not concealed by antitragus. Antitragus well developed, roughly rectangular. No gular gland. Wings and interfemoral membrane greyish-black.

Figure 114. *Tadarida gallagheri*. Skull (holotype; based on Harrison 1975).

Skull (Figure 114) not extremely dorsoventrally flattened. Rostrum relatively very long for a *Tadarida*, with prominent paired nasal swellings surrounding the nasal aperture. Anterior of braincase prominently elevated above plane of rostrum (Figure 99a). Sagittal crest absent; lambdoid crest weakly developed. Anterior palatal emargination closed, incisive foramina not visible in holotype. Basisphenoid pits deep, large, much wider than the narrow septum separating them. Dentition not robust. Upper incisors comparatively large, well separated. Anterior upper premolar ca. same height as cingulum of posterior premolar, within toothrow but lateral to cingulum of the canine; canine and posterior premolar well separated. M^3 with third ridge > half length of second. Two lower incisors on each side; not crowded; inner incisor larger and faintly bicuspid; outer incisor narrower and unicuspid. Lower canines slender; cingula not greatly enlarged and not in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation No information.

Similar Species Only one other *Tadarida* in the African region (and *T. johorensis* from Asia) has a bulbous lobe containing an interaural pocket projecting over the muzzle, and a rostrum with nasal swellings:

Tadarida tomensis. Known only from São Tomé I, in Gulf of Guinea (and therefore not profiled), but occurrence on mainland is possible. Bulbous lobe similar but not projecting quite as far forward. No folds of skin extending backwards out of the pocket and uniting on crown of head. Swellings surrounding nasal aperture smaller; nasal aperture longer (Juste & Ibáñez 1993b).

Distribution Known only from type locality in Rainforest BZ (South Central Region).

Habitat The only known specimen was collected in the vicinity of the village of Scierie (03° 10' S; 25° 49' E) near the west bank of the Congo R. It was mist-netted in a clearing within the thick, evergreen undergrowth of a partly deciduous forest, in which the secondary regrowth was well advanced. The forest had been heavily logged and only a few giant trees remained (Gallagher & Harrison 1977).

Remarks Wings long and narrow, therefore flight predictably fast and agile, but with poor manoeuvrability, as in other molossids. The extraordinary nasal swellings, which are reminiscent of those of *Rhinopoma*, are so distinctive that generic status should be considered for this bat (Harrison 1975). In most features, however, it represents a highly specialized *Chaerephon*, a swift-flying species that has developed some special modification of the nasal region for echolocation (Harrison 1975). The discovery of a ♀ is awaited with great interest as the structure of its ears may differ from that of the ♂. It is not inconceivable that the three female bats from São Tomé, described as *Tadarida tomensis* by Juste & Ibáñez (1993b), represent *T. gallagheri* but, if so, the species exhibits a marked and very unmolossid-like degree of sexual dimorphism, especially in the extent to which the interaural pouch and the nasal swellings are developed. Furthermore, the skulls and teeth of the two forms differ in other ways, for example the extent of the interorbital constriction, the sizes and shapes of the upper incisors and canines, and the size and depth of the basisphenoid pits (Juste & Ibáñez 1993b), and these differences are more likely to occur in different species than in different sexes of the same species.

Conservation IUCN Category: Data Deficient.

Known from only one location, and population reduction is predicted to occur based on decline in area of occupancy, extent of occurrence or quality of habitat (Hutson *et al.* 2001). Other collections in area have not found this species. Major threat: loss of habitat because of logging, clear-cutting and farming. However, possibly more widespread than presently believed.

Tadarida lobata BIG-EARED FREE-TAILED BAT

Fr. Tadaride du Kenya; Ger. Großohr-Bulldoggfledermaus

Tadarida lobata (Thomas, 1891). Ann. Mag. Nat. Hist., ser. 6, 7: 303. Turkwell Gorge, West Pokot, Kenya.

Taxonomy Originally *Nyctinomus lobatus*. Subgenus *Tadarida*. Synonyms: none. Chromosome number: not known.

Description Medium-small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; large for an African molossid; ears very large, meeting to form a V-shaped valley; wings greyish; ventral flank-stripe white; two lower incisors on each side; M³ with third ridge > half length of second ridge. Sexes almost similar; ♂ larger in some skull dimensions including C–M³. Pelage short, velvety. Dorsal pelage dark brown (various shades) with conspicuous white spot between shoulder-blades in all known fully mature adults, and variable amounts of white or pale pelage behind the junction of the ears; hairs bicoloured, base white, tip dark brown. Ventral pelage brown on flanks, very much paler (sometimes white) mid-ventrally; no mid-ventral markings; ventral flank-stripe fluffy, white, contrasting with flanks. Orange-phase: not known. Head not extremely flattened. Upper lip without well-defined wrinkles; comparatively few spoon-hairs (Freeman 1981). Ears semi-translucent pale greyish-brown; relatively large (extending well beyond snout when laid forward); inner margins meeting to form a V-shaped valley. Uniquely, the bases of the inner margins meet well forward on the muzzle where they join to form a membrane extending along muzzle almost as far as the snout (Figure 115). Tragus large, roughly rectangular, not concealed by antitragus. Antitragus moderate, roughly twice as big as tragus. No interaural crest. Gular gland present, equally developed in both sexes. Wings and interfemoral membrane semi-translucent, greyish dorsally, whitish ventrally. Ventral sides of forearms and legs naked and white. Foot with raised pad on sole (plantar pad).

Skull not extremely dorsoventrally flattened. Anterior of braincase only slightly elevated above plane of rostrum (Freeman 1981). Sagittal crest weakly developed in ♂♂, inconspicuous in ♀♀; lambdoid crests distinct in both sexes. Anterior palatal emargination wide. Interdental palate broad posteriorly, narrowing towards canines but not smoothly

– there is a marked constriction at level of posterior premolars (cf. *T. fulminans*). Basisphenoid pits shallow to moderate in depth, medium-sized, their width slightly greater to slightly less than their distance apart. Upper incisors moderate in length and close together. Anterior upper premolar distinctly taller than cingulum of posterior premolar, within tooththrow; canine and posterior premolar well separated. M³ with third ridge > half length of second ridge. Two lower incisors on each side; minute. Lower canines slender; cingula not enlarged, separated by the incisors. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Four other *Tadarida* in Africa have ears with inner margins meeting, or almost meeting, to form a V-shaped valley (Table 20, p. 488):

Tadarida aegyptiaca. Usually smaller (FA: 42–55 mm; GLS: 17.1–21.9 mm). Inner margins of ears almost meeting on forehead; ears not extending beyond snout when laid forward. No white spot between shoulder-blades.

T. fulminans. Inner margins of ears meeting on forehead; ears not extending beyond snout when laid forward. No white spot between shoulder-blades. Skull with interorbital constriction moderate; interdental palate only slightly constricted at level of posterior premolar. Lower canines with cingula nearly in contact.

T. teniotis. Three lower incisors on each side. Inner margins of ears meeting on forehead; ears not extending beyond snout when laid forward. Interdental palate not markedly constricted at level of posterior premolar. North Africa.

T. ventralis. Inner margins of ears meeting on forehead; ears not extending beyond snout when laid forward. No white spot between shoulder-blades. Skull with interorbital constriction pronounced. Anterior upper premolar minute; canine and posterior premolar nearly in contact. Lower canines well developed; cingula in contact.

Distribution Endemic to Africa. As yet, only recorded from Afromontane–Afroalpine and Somalia–Masai Bushland BZs in Kenya, and Zambezian Woodland BZ in Zimbabwe. In Kenya, recorded from four localities (including type locality) in the north-west, and Maungu Hill in the south-east. In Zimbabwe, recorded from the Sengwa Gorge, Siabuwa District in the north-west, from two localities (Borrowdale Brook & Hatfield) on outskirts of Harare (Cotterill 1996b), and recently from the Mutoko District, where specimens were mist-netted in 1997 and 1999 (Cotterill 2001c).

Habitat Woodland savannas with suitable sites for day-roosts. In Kenya, 19 individuals were taken on a large flat plain of open thorn scrub with scattered rocky hills including Maungu Hill, a high rock outcrop with deep crevices along its cliff face (A. Williams in Peterson 1974). In Zimbabwe, one was mist-netted on the wall of a dam near

Figure 115. Left ear of *Tadarida lobata* (based on Peterson & Harrison 1970).

*Tadarida lobata*

precipitous sandstone cliffs of the 10 km-long Sengwa Gorge; the vegetation is semi-arid, mainly *Combretum/Commiphora* scrub and mopane woodland (Cotterill 2001c). The Harare specimens were taken in miombo woodland within 20 km of small granite outcrops, and the Mutoko specimens from a mosaic of farmlands with miombo woodland in terrain dominated by large granitic inselbergs, many with precipitous sides. The Mutoko specimens were mist-netted over, or very near, open water.

Abundance Uncertain. *Tadarida lobata* is one of Africa's rarest and most enigmatic molossids. Despite its description in 1891, it remained known only by the holotype until single specimens were collected from Kenya and Zimbabwe in 1964 and 1969, respectively (Peterson & Harrison 1970). Two larger series of specimens were collected from these two countries subsequently. This species appears to be locally common (based on a series of 19 specimens shot at Maungu Hill, Kenya, by Peterson [1974]; and eight specimens mist-netted in the Mutoko District of Zimbabwe in 1997 and 1998 [Cotterill 2001c]).

Remarks Wings very long and very narrow, as in *T. fulminans* and *T. ventralis*. Flight fast, agile, with poor manoeuvrability. Flies fast and straight, or circles more slowly (Peterson 1974). Bats converging on the areas around two water tanks (? dams) in Kenya, uttered a distinctive single- or double-noted loud squeak, audible to humans; no more than 2–3 individuals were seen or heard at a time. Although obviously attracted to the water, none of the bats was seen to descend to drink, and none was caught in mist-nets set over the tank. Two specimens from Harare (Zimbabwe) were found dead in suburban gardens; eight others were mist-netted near open water in the Mutoko District (Zimbabwe) in association with *Sauromys petrophilus*, *T. ansorgei* and *T. fulminans*. Three of these were mist-netted within the first hour of darkness in Nov 1997 and Nov 1999. All eight were lactating ♀♀, suggesting parturitions had occurred in late Oct or early Nov.

Conservation IUCN Category: Least Concern.

New records in Zimbabwe suggest that *T. lobata* is more widespread and perhaps more abundant than estimated by Hutson *et al.* (2001).

Tadarida major LAPPET-EARED FREE-TAILED BAT

Fr. Tadaride à oreillettes; Ger. Stirnlappen-Bulldoggfledermaus

Tadarida major (Trouessart, 1897). Cat. Mamm. Viv. Foss. 1: 146. 5th Cataract of the Nile, N Sudan.

Taxonomy Originally *Nyctinomus pumilus* var. *major*. Subgenus *Chaerephon*. Synonyms: *abae*, *emini*. Subspecies: none. Similarities between the comparatively simple lappet between the ears of *T. major*, and the highly developed, forward-projecting lobe between the ears of *T. gallagheri* from DR Congo and *T. tomensis* from São Tomé, indicate a need to re-examine the relationships between these species, and between these species and other *Tadarida*. Chromosome number: not known.

Description Small to very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-small for an African molossid; ears separated by a distinctive lappet over an interaural pocket, which, in adult ♂♂, contains an interaural crest; M³ with third ridge > half second ridge; wings usually dark (rarely white or pale), ventral flank-stripe white or whitish. Sexes almost similar. Pelage short (mid-dorsal hairs ca. 3 mm), covering rump but not extending

onto interfemoral membrane. Dorsal pelage dark sepia brown, yellowish-brown, greyish-brown or dull rusty-brown; sometimes slightly grizzled but no white flecks or spots; hairs unicoloured, sometimes with white at tip. Ventral pelage similar becoming paler mid-ventrally; mid-ventral markings white, highly varied in size and shape; ventral flank-stripe white or whitish. Head not extremely flattened. Upper lip with 6–7 well-defined wrinkles on each side and many spoon-hairs. Ears dark brown or blackish; just reaching snout when laid forward; inner margins meeting to form V-shaped valley but, unlike other African *Tadarida*, there is a conspicuous, flat, subtriangular or roughly semi-circular flap (= lappet or lobe) projecting backwards between the inner margins of the ears: this forms a lid over a small pocket that opens posteriorly (Figure 97). In adult ♂♂, the pocket under the lappet is lined by short (7 mm) rusty-brown hairs, which form an interaural crest. Tragus small, squarish, concealed by antitragus. Antitragus large, tall, almost rectangular but with top corners rounded. No gular gland. Wings semi-translucent, with varying degrees of dark brown or black pigmentation in most individuals – the holotype, however, has white wings (Rosevear 1965). Interfemoral membrane dark brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase not noticeably elevated above plane of rostrum. Sagittal crest low or absent; lambdoid crest moderate. Anterior palatal emargination slightly open (in young adults) or closed. Basisphenoid pits shallow to moderately deep, variable in size – sometimes elongated and ca. half as wide as their distance apart, sometimes oval and as wide as their distance apart. Anterior upper premolar ca. same height as cingulum of posterior premolar or lower or higher, within toothrow; canine and posterior premolar separated. M³ with third ridge equal to, or just over, half length of second. Two lower incisors on each side; bicuspid, somewhat crowded. Lower canines with cingula not greatly enlarged and either in contact or not in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species No other African *Tadarida* has a flat lappet over an interaural pocket between the ears.

Distribution Endemic to Africa. Distribution appears disjunct. Recorded from Sahel Savanna, Sudan Savanna and Guinea Savanna BZs and the Northern Rainforest–Savanna Mosaic, and from one locality in the Rainforest BZ (Western Region), from W Liberia to S Niger and Nigeria. Also occurs in these biotic zones, and also in the Sahara Arid BZ, in the valleys of the Nile R. and its tributaries in Sudan, in the Rainforest–Savanna Mosaics in NE DR Congo, Uganda, Kenya and Tanzania, and in the Coastal Forest Mosaic BZ in Kenya and Tanzania. It is not known if the apparent gap between ca. 10°E and 33°E reflects insufficient collecting or the absence of the species from this area for some unknown reason. Simmons (2005) indicates the occurrence of *T. major* in Senegal but without details. Mapped from country checklists (see order Chiroptera), other literature and museum records. Subsequently recorded widely in the south-western half of Uganda (Thorn & Kerbis Peterhans 2009): not mapped.

Habitat Recorded mainly from woodland and grassland savanna vegetation zones including undifferentiated woodland, *Isoberlinia*

Tadarida major

woodland, Sahel *Acacia* wooded grassland and deciduous bushland, and *Acacia–Commiphora* deciduous bushland and thicket, and from riverine habitats along the Nile R. and its tributaries (terminology: White 1983). Also recorded from areas of invasive grassland in the mosaic of rainforest and secondary grassland in West Africa and NE DR Congo, and from the Coastal Forest Mosaic BZ (but not within the coastal forests).

Abundance Uncertain.

Adaptations The wings are long and narrow implying flight characteristics similar to those of other species of *Tadarida*. By day, roosts in dark crannies within rocky clefts in hills, in hollows formed by aggregations of boulders, in hollow trees, lofts of houses and holes in walls of buildings (Lang & Chapin 1917b, Rosevear 1965). Roosts are sometimes revealed by their musty smell and the incessant squeaking of their occupants. Lang & Chapin (1917b) noted that disturbed bats seemed intent on returning to their habitual roosts, suggesting that roost-fidelity is high. Emergence occurs well before nightfall (Rosevear 1965). The triangular lappet between the ears is usually laid backwards and, in the ♀, covers a hairless spot. In the ♂, it can be erected to expose the interaural crest. The hairs of the crest are thicker than those of the body, and structurally resemble scent-dispersing hairs (osmetrichia) (Hickey & Fenton 1987), which suggests that they might arise from glandular tissue, but the contexts in which the crest is erected are not yet known.

Foraging and Food No information. Predictably forages by fast-hawking.

Social and Reproductive Behaviour Roosts in groups of ca. four to more than 100. Rosevear (1965) suggests size of groups depends on available accommodation. Only two of many more than 30 individuals captured together were ♂♂ (Lang & Chapin 1917b),

but the reproductive condition of these bats was not published and the social organization of this species is not known.

Reproduction and Population Structure No information.

Predators, Parasites and Diseases Ectoparasites include fleas *Lagaropsylla anciauxi*, *L. taeniolae* (Siphonaptera: Ischnopsyllidae); a tick *Carios confusus* (Acari: Argasidae); and a mite *Chelanyssus aethiopicus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984, Beaucournu & Kock 1996).

Conservation IUCN Category: Least Concern.

Tadarida midas MIDAS FREE-TAILED BAT

Fr. Tadaride midas; Ger. Midas-Bulldogfledermaus

Tadarida midas (Sundevall, 1843). Kongl. Svenska Vet.-Akad. Handl. Stockholm 1842: 207 [publ. 1843]. Jebel el Funj, White Nile River, West Bank, Blue Nile [= Bahr-el-Abiad Prov.], Sudan.

Taxonomy Originally *Dysopes midas*. Subgenus *Mops*. Synonyms: *unicolor*, *miarensis*. Subspecies: two; only one in Africa (but see Geographic Variation). Chromosome number (Somalia, Namibia, South Africa): 2n = 48; aFN = 66 (Smith *et al.* 1986; Rautenbach *et al.* 1993).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; large, robustly built and particularly heavy for an African molossid (FA: 59–67 mm; WT: 38–69 g); ears joined by interaural band; M³ with third ridge absent; anterior palatal emargination closed; wings dark brown; ventral pelage greyish-brown to silvery-grey; ventral flank-stripe white or pale. Sexes almost similar. Pelage short (mid-dorsal hairs 5–6 mm), silky, sparse; nape almost naked. Dorsal pelage (grey-phase) dark brown, medium sepia brown, pale brown or pale grey with pale grey or white frosting and flecking; hairs with paler base and mostly with white or pale grey tip. Crown same colour as back. Ventral pelage greyish-brown, pinkish-brown to silvery-grey, frosted (subadults almost white); no mid-ventral markings; ventral flank-stripe white or paler than ventral pelage. Orange-phase: dorsal pelage reddish to almost orange. Pelage colouration apparently uniform within colonies, but Verschuren (1957) found two colonies roosting in the same tree, whose members had distinctly different colours. Head not extremely flattened. Upper lip with 5–6 well-defined wrinkles on each side and many spoon-hairs. Ears blackish-brown, relatively large (extending just beyond snout when laid forward); inner margins joined over muzzle by interaural band with a V-shaped fold and a forward-projecting pocket-like invagination, which protrudes ca. half-way along muzzle. Tragus small, squarish or hatchet-shaped; concealed by antitragus. Antitragus large, semi-circular. Males and ♀♀ with interaural crest of longer, brown hairs arising from the interaural

pocket. No gular gland. Wings and interfemoral membrane dark brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase moderately to prominently elevated above plane of rostrum (Figure 99c). Sagittal crest moderately to well developed in both sexes; lambdoid crests well developed and forming a prominent helmet in adult ♂♂, weakly to moderately developed in ♀♀. Anterior palatal emargination closed; incisive foramina visible. Basisphenoid pits moderately deep, medium-large, their width varying from equal to their distance apart to almost twice their distance apart. Anterior upper premolar variable in size (lower to taller than the cingulum of the posterior premolar), within tooththrow. M³ with third ridge absent. Two lower incisors on each side, bicuspid, crowded or not crowded. Lower canines with cingula not greatly enlarged, sometimes well separated, sometimes almost in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Two subspecies are recognized by Koopman (1994):

T. m. midas. Throughout African geographic range.

T. m. miarensis. Madagascar.

However, based on molecular genetics, the Madagascan and African populations are not distinct (Goodman 2011).

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge present (but usually* < half length of second ridge) or absent; anterior palatal emargination closed; FA: >40 mm (Table 20, p. 488). *In *T. condylura*, the length of the third ridge is variable and can be up to half length of second ridge.

T. condylura. Much smaller and lighter (FA: 45–51 mm; WT: 16–39 g).

Tadarida congica. Forearm shorter (54–58 mm). Dorsal pelage less variable, dark brown to black; not frosted and without whitish flecking. Skull of similar length but less robust and often narrower (GWS: 14.8–16.3 mm).

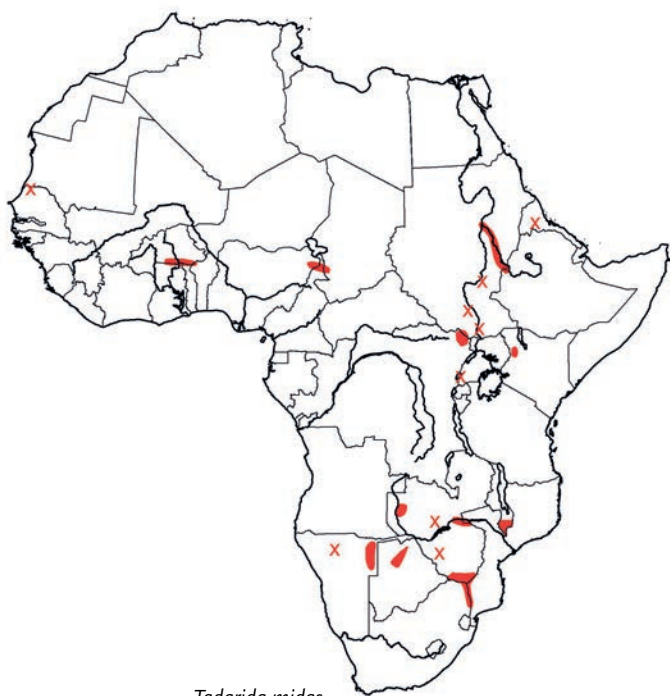

T. demonstrator. Much smaller and lighter (FA: 41–46 mm; WT: 20–24 g).

T. niveiventer. Much smaller and lighter (FA: 44–48; WT: 20–30 g).

T. trevori. Smaller (FA: 51–55 mm; GLS: 23.1–25.1 mm). M^3 with third ridge present (but < half length of second ridge).

Distribution In Africa, recorded from very scattered localities mainly in Sudan Savanna, Guinea Savanna and Zambezan Woodland BZs, with some records marginally in Sahel Savanna, Somalia–Masai Bushland and South-West Arid BZs, and the Rainforest–Savanna Mosaic in NE DR Congo. Recorded from Senegal to Eritrea and Ethiopia (but not from all countries) and southwards through S Sudan, NE DR Congo and W Kenya, and further southwards in N Namibia, SW Zambia, Botswana, Zimbabwe, S Malawi and NE South Africa. Distribution often follows major rivers and rift valleys including the Blue Nile R. in Sudan, the upper reaches of the White Nile R. and the East African Rift Valley, the Shire Valley in Malawi, and the valleys of the Zambezi R. and its tributaries, and the Limpopo R. in southern Africa. Gaps in distribution probably reflect insufficient sampling. Map based only on published records including Dorst (1959), Hayman *et al.* (1966), Smithers (1971), Vielliard (1974), Koopman (1975), Bergmans (1977b), Koopman *et al.* (1978), Ansell (1978), Cotterill (1996b) and others, and some museum records. Kingdon (1974), Smithers (1983) and Dunlop (1999) mapped vast areas (especially north of Equator) for which there appear to be no records. Extraliminally: Saudi Arabia, Madagascar.

Habitat Open woodland savannas (including Sudanian undifferentiated woodland, *Isoberlinia* woodland and drier miombo

woodland), grassland savannas and, in the Kalahari Desert, the transition zone from undifferentiated woodland to *Acacia* bushland and wooded grassland. Almost always found near major rivers and wetlands including the Sudd in Sudan, the Okavango Swamp in Botswana and the Shire R. and its marshes in S Malawi. Evidently avoids closed forests. Not dependent on rocky, hilly or mountainous terrain for its day-roosts.

Abundance Uncertain. Not very plentiful in collections (Rosevear 1965). Rarely recorded in Malawi (Happold & Happold 1997). Common, locally, in NE Botswana and Limpopo Valley (Zimbabwe) (Cotterill 1996b). Elsewhere: no information.

Adaptations Wings long and narrow. Flight fast, agile with poor manoeuvrability. Roosts by day in pitch-dark attics, in hollow cement bricks of the walls of buildings, in dimly lit expansion joints of bridges, under corrugated-iron roofs and, in DR Congo, in very long, narrow fissures penetrating deeply into the trunks or large branches of trees (particularly *Vitex* and *Parinari*) (Verschuren 1957, Smithers 1971, Smithers & Wilson 1979, Rautenbach 1982, Fenton & Rautenbach 1986). In DR Congo, not found roosting in rock-crevices that were available (Verschuren 1957). Entrances must be accessible by direct flight, and high enough to allow the bats to dive when they leave the roost. Apparently not reported to share roosts with other species of bats except in Kruger N. P., South Africa, where a roost was shared with *T. condylura* and *T. pumila*. At Faradje, NE DR Congo, only present for a short period at end of dry season: small beetles (prey) were common at that time (Lang & Chapin 1917b).

Foraging and Food Forages by fast-hawking in open spaces including over canopies, open water (rivers, swamps, flooded pans) and open plains. In DR Congo, individuals emerged at dusk and did not return to the day-roost until just before sunrise (Verschuren 1957). In Mar, ca. 12 were observed arriving about dusk to forage 15–30 m above the Dungu R.; they flew at high speed, and dodged and dived after small hard-shelled beetles, which were then common; stomachs of some of these bats contained remains of these beetles that had been masticated in flight (Lang & Chapin 1917b). In Botswana, observed flying 30–40 m above ground, and swooping down to a waterhole to take insects (Smithers 1971, 1983). In Kruger N. P., South Africa, radio-tracked individuals seemed to move at least 10 km from their day-roost; of 15 foraging flights observed, five (in immediate vicinity of roost) lasted <10 min, ten lasted 51.7 ± 41.1 min; there was no evidence that foraging behaviour changed according to moonlight (Fenton & Rautenbach 1986). The stomach of one individual from Botswana contained fragments of beetles (Archer 1977).

Echolocation Search-phase call-shape (South Africa): shallow FM. Start frequency 30 kHz; end-frequency not known (Aldridge & Rautenbach 1987).

Social and Reproductive Behaviour In DR Congo, has been observed foraging in groups of ca. 12 individuals (Lang & Chapin 1917b), and groups roosting together emerge together at dusk and also return within a minute of each other very shortly before sunrise (Verschuren 1957). Roosts in medium-sized to very large colonies; in DR Congo, colonies of 20–30 were reported by Verschuren (1957);

in southern Africa, colonies of 'dozens' and 'several hundreds' were reported by Smithers (1971) and Smithers & Wilson (1979). In DR Congo, the ratio of ♂♂ to ♀♀ in colonies taken from roosts was 1 : 3.6; in contrast, samples taken as bats emerged from a roost in Botswana contained ca. equal numbers of both sexes (Smithers 1971). In roosts, these bats are restless and utter squeaks (audible to humans) at all hours of the day. Verschuren (1957) noted that some trees housed more than one colony, each occupying a separate site and using a separate entrance.

Reproduction and Population Structure Litter-size (Malawi, Botswana): one ($n = 16$). Reproductive chronology not known. Near the Equator in S Uganda, 5 of 5 ♀♀ were in early pregnancy in Jan, 1 of 1 was lactating in Mar, 1 of 1 was post-lactating in Jun, and 1 of 1 had recently given birth in Oct: these data suggest that births occur during two seasons in this locality (Kingdon 1974), but this needs confirmation. At 20° 00' S (Okavango Swamp, Botswana), samples of 3, 3, 14 and 5 ♀♀, taken from an attic in Mar, Apr, Jun and Sep, respectively, contained only non-pregnant ♀♀; in Dec, 1 of 16 was pregnant, in Jan, 6 of 13 were pregnant and in Feb, 7 of 18 were pregnant (all others 'non-gravid') (Smithers & Wilson 1971). Additional records from Okavango Swamp, W Zambia and S Zimbabwe include four early pregnancies in Oct, four late pregnancies in mid-Nov, two ♀♀ lactating (and four non-volant juveniles) in Dec, and one lactating ♀ and one naked but volant juvenile in Apr. These data suggest that, in Botswana and nearby, births only occur in Dec–Mar, but whether the chronology is extended seasonal monoestry, or polyoestry, remains to be determined.

Predators, Parasites and Diseases Ectoparasites include fleas *Lagaropsylla hoogstraali*, *L. idae* (Siphonaptera: Ischnopsyllidae) and

mites *Chelanyssus aethiopicus* (Acari: Macronyssidae), *Ewingana nanula* (Acari: Myobiidae) and *Nycteriglyphus tadaridae* (Acari: Rosensteiniidae) (Anciaux de Faveaux 1984, Segerman & Braack 1988).

Conservation IUCN Category: Least Concern.

Probably threatened by destruction of woodland in parts of its geographic range.

Tadarida nanula DWARF FREE-TAILED BAT

Fr. Tadaride naine d'Afrique; Ger. Zwerg-Bulldoggfledermaus

Tadarida nanula (J. A. Allen, 1917). Bull. Am. Mus. Nat. Hist. 37: 477. Niangara, Orientale, DR Congo.

Taxonomy Originally *Mops (Allomops) nanulus*. Subgenus *Xiphonycteris*. According to Koopman (1989), the distinction between *nanulus* and *spurrelli* is far from certain and depends largely on the greater degree of sexual dimorphism in dental characters in adult *T. spurrelli* compared with that in *T. nanula*. In contrast, El-Rayah (1980, 1981) demonstrated that *T. nanula* is distinct. Synonym: *calabarensis*. Subspecies: none. Chromosome number (Cameroon): $2n = 48$; $aFN = 54$; one pair large metacentric, two pairs small metacentric, one pair medium subtelocentric and 19 pairs medium-small acrocentric autosomes (Smith *et al.* 1986).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; one of the two smallest African *Tadarida* (FA: 27–31 mm); ears joined by interaural band; M³ with third ridge absent; anterior palatal emargination narrow; wings semi-translucent, whitish or brownish; ventral pelage moderately pale; no ventral flank-stripe in contrasting colour; canines without greatly enlarged cingula. Females not easily distinguished from female *T. spurrelli*. Sexes almost similar.

Pelage short (mid-dorsal hairs ca. 2 mm); dorsal pelage extending over most of rump but not quite reaching interfemoral membrane. Dorsal pelage varying from bright orange-brown to blackish-brown (Rosevear 1965), no grizzling, no spots; hairs cream with orange-brown to blackish-brown at tip. Rump with two tufts of long hairs (as in several other *Tadarida*). Ventral pelage with flanks brown, belly pale reddish-brown, yellowish-brown or brownish-grey; mid-ventral markings white, pale yellowish-brown or pale grey, variable in shape, not sharply delineated but merging with flank colour, sometimes covering most of ventral surface, sometimes absent; no ventral flank-stripe in contrasting colour. Head not extremely flattened. Upper lip with 5–6 well-defined wrinkles on each side and many spoon-hairs. Ears blackish becoming paler near base, reaching just over half-way along muzzle when laid forward; inner margins joined by interaural band with forward and downward-pointing V-shaped fold in middle. Tragus very small, pointed, concealed by antitragus. Antitragus large; roughly trapezoid. Interaural band supporting dense, dark brown hairs that are slightly coarser than body hairs and are longer in ♂♂ than in ♀♀. Gular gland: no information. Wings semi-translucent,

sometimes with light to moderate white pigmentation, sometimes pale brown, sometimes blackish-brown with varying amounts of pigmentation. Interfemoral membrane brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase only very slightly elevated above plane of rostrum (Figure 99g). Sagittal crest low or absent; lambdoid crest low to well developed and forming a helmet, especially (but not solely) in old ♂♂ (Rosevear 1965). Anterior palatal emargination narrow, bulb-shaped (narrowest between incisors). Basisphenoid pits shallow, small, their width less to much less than their distance apart. Upper incisors (Figure 104a) are procumbent (angled slightly forward). They occupy the most anterior edge of the premaxillae and therefore are not in same plane as the canines (cf. *T. spurrelli*) (El-Rayah 1980). Upper canines with cingula not enlarged: when viewed laterally, the upper incisors are visible – not hidden by the canine cingula (cf. ♂ *T. spurrelli*). Anterior upper premolar distinctly taller than cingulum of posterior premolar, within toothrow or somewhat displaced lingually. M³ with third ridge absent. Two minute lower incisors on each side. Lower canines long and robust; cingula not greatly enlarged and not in contact. Anterior lower premolar larger than posterior premolar in ♂♂; smaller than posterior premolar in ♀♀ (Allen 1917a). Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded. Possibly wing colour varies geographically (whitish in West Africa, brown to dark brown in DR Congo and East Africa) but this needs confirmation.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge absent or present but < half length of second; palatal emargination narrow; FA almost always less than 40 mm (Table 20, p. 488):

Tadarida brachyptera. Forearm longer (35–38 mm). M³ with third ridge present but < half length of second. Upper incisors not procumbent.

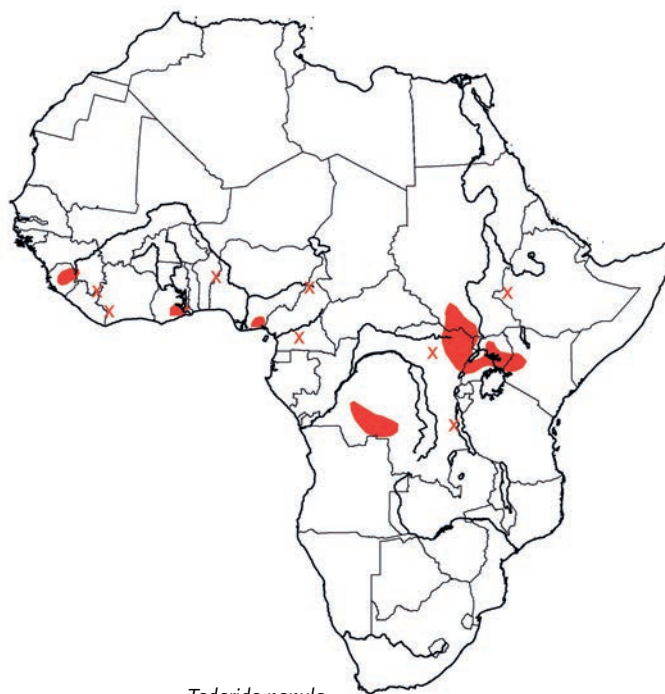

T. petersoni. Forearm longer (34–41 mm). M³ with third ridge present but < half length of second. Basisphenoid pits moderate in depth, larger and closer together.

T. spurrelli. Wings dark brown or blackish. Ventral pelage white merging into brown on flanks. Upper canines with enlarged cingula: when viewed laterally the upper incisors are hidden by the canine cingula in ♂♂, but partly visible in ♀♀. In adult ♂♂ and some adult ♀♀, cingula of lower canines greatly enlarged and in contact, forming an arch over the minute incisors. Usually one lower incisor on each side.

T. thersites. Forearm longer (35–42 mm). Ventral pelage very dark. M³ with third ridge present but < half length of second ridge.

See also *T. bakarii* in profile of *T. brachyptera*.

Distribution Endemic to Africa. Recorded disjunctly from Rainforest BZ and Rainforest–Savanna Mosaics from Sierra Leone to E DR Congo and Uganda, and in S DR Congo (but not recorded from all countries), and from the Afromontane–Afroalpine BZ in Ethiopia and W Kenya. Erroneously recorded from Gambia (J. Fahr in Simmons 2005). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Tadarida nanula

Habitat Recorded mainly from various habitats near edges of lowland rainforest (Rosevear 1965). Often recorded near large rivers (perhaps because, in the past, they could be captured over water more easily than in other places). Occasionally recorded in woodland savannas (often near rivers). For example, recorded in *Combretum–Terminalia* woodland near riverine forest on Baro R., at 515 m in Ethiopia (Largen *et al.* 1974), and in light riverine forest by Wei Wei R. in 'dry grassy *Acacia* country' in Kenya (Start 1969).

Abundance Uncertain.

Remarks Has been found roosting by day in hollow trees, in thatch and inside buildings, but not under corrugated iron roofs (Lang & Chapin 1917b, T. S. Jones in Rosevear 1965, Grubb *et al.* 1998). One was found 'hanging down' in a clump of bamboo (T. S. Jones in Rosevear 1965) but this is unlikely to be normal roosting behaviour. Has been found singly, but more often in groups, usually of uncertain size and composition. One group included three adult ♂♂ and three ♀♀ and others (Lang & Chapin 1917b). A group of nine taken from a crack in a tree were all ♀♀ with very large embryos or neonates, suggesting that *T. nanula* might establish maternity colonies (T. S. Jones in Rosevear 1965). At 1–2°N in Kenya, 5 of 6 ♀♀ were heavily pregnant and one was lactating and also pregnant (with one embryo) in late Aug (Start 1969 and BMNH). In Uganda, this species appears to have two birth seasons a year, with births in late Mar–Apr, and Sep (Kingdon 1974), but no evidence is given and this suggestion needs confirmation.

Predators, Parasites and Diseases Ectoparasites include fleas *Lagaropsylla obliqua*, *L. convexa* (Siphonaptera: Ischnopsyllidae) and a mite *Ewingana nanula* (Acari: Myobiidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Threatened, however, by loss of habitat in the western part of the geographic range.

Fr. Tadaride de Niangara; Ger. Niangara-Bulldoggfledermaus

Tadarida niangarae (J. A. Allen, 1917). Bull. Am. Mus. Nat. Hist. 37: 468. Niangara, DR Congo.

Taxonomy Originally *Mops niangarae*. Placed in subgenus *Mops*. Synonyms: none. The specific status of *T. niangarae* is uncertain. Considered to be a subspecies of *T. congica* by Hayman & Hill (1971). Included in *Tadarida trevori* by Peterson (1972) (for reasons, see Description) and Koopman (1994). Tentatively considered to be a distinct species (pending examination of further specimens and a more formal revision of the *trevori/congica* complex) by Freeman (1981) and Simmons (2005). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid; ears originally described as well separated (but see below); M³ with third ridge present but < half second ridge; anterior palatal emargination closed; wings dark; probably no ventral flank-stripe in contrasting colour. Known only from the holotype (♂, skin and skull). Pelage short. Dorsal pelage uniform rusty-brown, no grizzling, no spots; hairs much paler at base. Ventral pelage yellowish-brown, paler and more yellowish on chest; mid-ventral markings and ventral flank-stripe in contrasting colour are not mentioned in type description and therefore are probably absent. Head not extremely flattened. Upper lip with more than seven wrinkles on each side and many spoon-hairs. Ears dark brown, described as well separated by Allen (1917a), but Peterson (1972) concluded that the apparent lack of an interaural band between the inner margins is an artefact of preparation. He concluded that there is an interaural band and that it is a fold of skin lacking cartilaginous support (as in *T. trevori*). The holotype appears to have a broad, low interaural crest of lengthened hairs, similar in colour and texture to those of dorsal pelage, but the shape has possibly been distorted in preparation. Tragus minute. Antitragus small, low. Gular gland: no information. Wings and interfemoral membrane dark brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum. Sagittal crest moderate; lambdoid crest very well developed and forming a helmet (Peterson 1972). Anterior palatal emargination closed; incisive foramina visible. Basisphenoid pits deep, large, their width ca. twice their distance apart. Anterior upper premolar almost as high as cingulum of posterior premolar, within toothrow; canine and posterior premolar well

separated. M³ with third ridge present but < half length of second ridge. Two minute lower incisors on each side. Lower canines not specially modified, cingula not enlarged. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation No information.

Similar Species This species of *Tadarida* would be unique if it has well-separated ears (i.e. inner margins not joined by interaural band) together with M³ with third ridge < half second, and anterior palatal emargination closed. However, if the inner margins of the ears are joined by a fold of skin lacking cartilaginous support, it is very similar to, and possibly conspecific with, *T. trevori*.

Distribution Known only from Niangara, DR Congo, which is in the Northern Rainforest–Savanna Mosaic very close to the Rainforest BZ.

*Tadarida niangarae*

Habitat Mosaic of lowland rainforest and secondary grassland.

Abundance No information.

Remarks Lang & Chapin (1917b) reported: 'It is one of many species that live in hollow trees and probably will be found to occur elsewhere in the more open country of the northern Uele.'

Conservation IUCN Category: Data Deficient.

Only one specimen known, but it is not certain that it represents a valid species.

Tadarida nigeriae NIGERIAN FREE-TAILED BAT

Fr. Tadaride du Nigeria; Ger. Nigeria-Bulldoggfledermaus

Tadarida nigeriae (Thomas, 1913). Ann. Mag. Nat. Hist., ser. 8, 11: 319. Zaria Province, Northern Region, Nigeria.

Taxonomy Originally *Chaerephon nigeriae*. Subgenus *Chaerephon*. Synonym: *spillmani* (described as a distinct species, but considered conspecific by Koopman [1965, 1975], Simmons [2005] and others). Subspecies: two. Chromosome number (Zimbabwe, Namibia): 2n = 48; aFN = 68; and described as karyotypically similar to *Sauromys petrophilus* (Rautenbach *et al.* 1993).

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid (FA: 41–51 mm); ears joined by interaural band; M³ with third ridge > half length of second; wings pale or dark; ventral flank-stripe white in marked contrast to ventral pelage; ♂♂ with short unicoloured interaural crest. Sexes similar. Pelage short (mid-dorsal hairs ca. 4 mm), dense; sparse between shoulder-blades. Dorsal pelage blackish-brown; no spots, rarely flecking; hairs unicoloured. Ventral pelage blackish-brown; no mid-ventral markings; ventral flank-stripe white, very conspicuous. Head not extremely flattened. Upper lip with 5–7 (*T. n. spillmani*) or 7–8 (*T. n. nigeriae*) well-defined wrinkles on each side and many spoon-hairs. Ears blackish, relatively medium-sized (almost reach snout when laid forward); inner margins joined by interaural band with backward-opening pocket-like invagination in middle. Tragus small, rectangular with top side straight or markedly concave, almost fully concealed by antitragus. Antitragus much larger than tragus, roughly trapezoid but top corners sometimes rounded. In adult ♂♂, the pocket in the interaural band contains an interaural crest of dark brown or dark rusty-brown hairs ca. 6 mm long. No gular gland. In *T. n. nigeriae*, wing-membranes blackish-brown dorsally, whitish ventrally especially close to body; interfemoral membrane blackish-brown. In *T. n. spillmani*, wings whitish and semi-translucent dorsally and ventrally, or blackish (Ansell 1960b); interfemoral membrane dark brown dorsally, paler ventrally. Skin on forearm dark brown dorsally extending narrowly onto wing-membrane as faint dark stripe. Further information in Willis *et al.* (2002).

Skull low but not extremely dorsoventrally flattened. Anterior of braincase not elevated above plane of rostrum. Sagittal crest very weakly developed; lambdoid crest well developed. Anterior palatal emargination closed. Basisphenoid pits shallow to moderate in depth, small to medium-sized, their width equal to, or less than, their distance apart (n = 9; BMNH). Anterior upper premolar usually rising higher than cingulum of posterior premolar, within tooth-row or somewhat displaced; canine and posterior premolar well separated. M³ with third ridge > half length of second. Two lower incisors on each side, bicuspid, sometimes crowded. Lower canines with cingula not greatly enlarged, not in contact but sometimes nearly so. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Two subspecies (similar in size) are recognized (Koopman 1965, 1994, Hayman & Hill 1971):

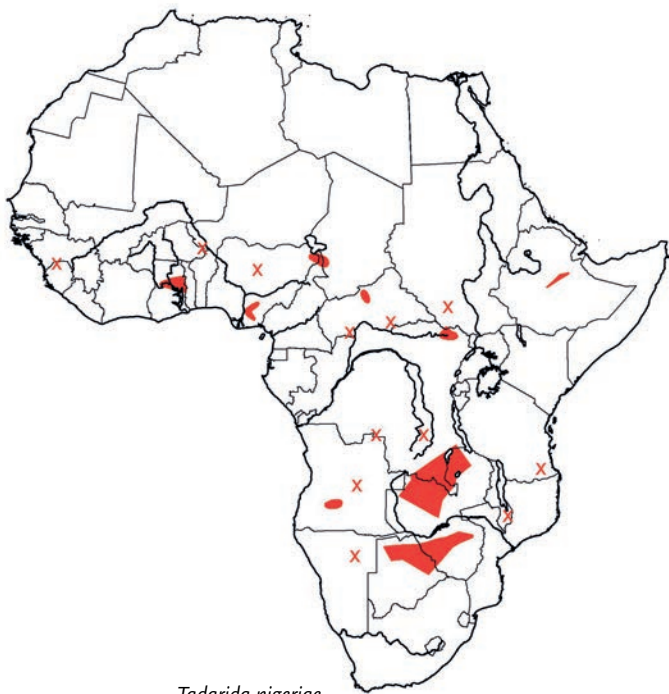

T. n. nigeriae: Sierra Leone to Ethiopia (extraliminally SW Arabia).

Wings dark brown.

T. n. spillmani: Angola to Tanzania and southwards to N Namibia and N Botswana. Wings whitish or blackish.

Similar Species None. No other African *Tadarida* has the following combination of characters: ears joined by interaural band; M³ with third ridge > half length of second; ventral flank-stripe white and in marked contrast with dark brown ventral pelage; no tail-glands; FA: 44–51 mm.

Distribution In Africa, *Tadarida n. nigeriae* is recorded from scattered localities in Sudan Savanna and Guinea Savanna BZs, Northern Rainforest–Savanna Mosaic and marginally in Rainforest BZ, from Sierra Leone to NE DR Congo and S Sudan (but not all countries), and in Somalia–Masai Bushland BZ and marginally in Afromontane–Afroalpine BZ, of the Ethiopian Rift Valley and Ethiopian Highlands. Extraliminally: Saudi Arabia (Harrison & Bates 1991). *Tadarida n. spillmani* is endemic to Africa. Recorded mainly

*Tadarida nigeriae*

from Zambezian Woodland BZ and marginally from Southern Rainforest–Savanna Mosaic and Kalahari Desert. Recorded from Angola, S DR Congo, Zambia, S Tanzania, N Namibia, N Botswana, Zimbabwe and S Malawi. Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat *Tadarida n. nigeriae* is mostly recorded from savanna woodlands and from areas where lowland rainforest has been partly or completely degraded to Guinea woodland (Rosevear 1965). *Tadarida n. spillmani* has been recorded in *Acacia*, mopane and miombo woodlands, often in association with permanent water.

Abundance *Tadarida n. nigeriae*: Appears comparatively rare: poorly represented in collections. However, it was the species most commonly found roosting in bungalows in Umuahia (Nigeria) (Cozens & Marchant 1952).

Tadarida n. spillmani: Locally common in NE Botswana, Namibia and Zambia, but remains poorly represented in collections.

Adaptations Aspect ratio very high; wing-loading high ($n = 1$, Malawi). Flight predicted to be fast and agile with poor manoeuvrability. In West Africa, day-roosts include roofs (permanent and thatched) and eaves (Rosevear 1965). In southern Africa, it has been found by day under exfoliating bark of dead trees (including trees standing in water); the moderately flattened skull of this species, and other *Tadarida*, facilitates roosting in such places. Also reported roosting in a small cave (Smithers 1971). In Botswana, one roost under bark (see below) was shared with five adult *Pipistrellus* sp.

Foraging and Food Based on wing morphology, predicted to forage by fast-hawking and to feed on flying insects. Has been mist-netted over muddy pools and on the bank of a farm dam in Malawi (Happold & Happold 1997); not known if coming down to drink or to forage.

Echolocation Search-phase call-shape (Zimbabwe): shallow FM. Start-frequency 26 kHz; end-frequency 16 kHz; peak-frequency 17 kHz; intensity high; maximum duration 10 ms (three bats, flying free; Fenton & Bell 1981).

Social and Reproductive Behaviour *Tadarida n. nigeriae* roosts in colonies (no details available) (Rosevear 1965). Bats roosting in the roof of a house in Nigeria started rustling and squeaking ca. half an hour before dark, and ca. 10 min later most left the roost together; later they would return and after dark some would hunt near the house; some kept up a round-the-eaves circuit (Cozens & Marchant 1952). *Tadarida n. spillmani* also roosts in groups or colonies; in Zimbabwe, a group of six emerged from a roost under bark (Smithers 1983); in Botswana, a colony roosting under bark included more than 25 adults (of which at least 13 were lactating ♀♀) and neonates and furred juveniles (FA: 29–35 mm) (P. J. Wright & M. Jarvis pers. comm.). In Zambia, sometimes found in large colonies (by definition 30–100 individuals) (Ansell 1960b).

Reproduction and Population Structure Litter-size (Namibia): one ($n = 8$) (ZFMK). Reproductive chronology: not known. In southern Africa, pregnant ♀♀ have been recorded in late Oct (Zimbabwe), lactating ♀♀ in mid-Nov (W Zambia) and in mid-Dec (Okavango Swamp, Botswana) and 8 of 10 ♀♀ pregnant (near term) in late Jan (NW Namibia) (F. P. D. Cotterill unpubl., ZFMK). The data suggest births in wet season, but data for other months are not available.

Predators, Parasites and Diseases Ectoparasites include fleas *Lagaropsylla lipsi*, *L. idae* (Siphonaptera: Siphonopsyllidae) and mites *Spinturnix walkeri* (Acari: Spinturnicidae), *Chelanyssus longisetosus*, *Steatonyssus crassisetosus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

In West Africa, the ability of this species to roost in buildings and to exploit cleared rainforest suggests that it may be comparatively resistant to anthropogenic impacts (Willis *et al.* 2002). In southern Africa, however, populations of this tree-roosting microbat are likely to be threatened by destruction of woodland in parts of its geographic range.

***Tadarida niveiventer* WHITE-BELLIED FREE-TAILED BAT**

Fr. Tadaride à ventre blanc; Ger. Weißbauch-Bulldoggfledermaus

Tadarida niveiventer (Cabrera and Ruxton, 1926). Ann. Mag. Nat. Hist., ser. 9, 17: 594. Luluabourg, Kasai Occidental Province, DR Congo.

Taxonomy Originally *Mops angolensis niveiventer*. Subgenus *Mops*. Synonym: *chitauensis*. Subspecies: none. Long considered a synonym or subspecies of *T. condylura*, until its specific status was confirmed by Koopman (1966) and Ansell (1967). Koopman (1975, 1993) suggests that *niveiventer* is 'probably a subspecies of *demonstrator*'. Considered to be a distinct species by Van Cakenberghe *et al.* (1999) and Simmons (2005). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-sized for an African molossid (FA: 44–48 mm); ears joined by interaural band; M³ with third ridge absent; anterior palatal emargination closed; wings pale; ventral pelage predominantly pure white or cream; no ventral flank-stripe in contrasting colour; crown darker than back; first phalanx of third and fourth finger intermediate in length (cf. only *T. demonstrator*, *T. condylura*). Not easily distinguished from *T. demonstrator*. Sexual dimorphism: uncertain. Pelage short (mid-dorsal hairs ca. 4 mm), glossy. Dorsal pelage dark brown or paler chocolate brown, often frosted (especially in dark brown individuals), sometimes flecked (especially in chocolate brown individuals); hairs dark brown or chocolate brown, sometimes with whitish tip. Crown and neck black or very dark brown – distinctly darker than back (as in *T. demonstrator*). Ventral pelage usually cream to pure white; no mid-ventral markings; ventral flank-stripe cream or white. Neonates with pale skin (cf. *T. condylura* at least in south-central Africa where sympatric with *T. niveiventer*). Head not extremely flattened. Upper lip with 5–6 well-defined wrinkles and many spoon-hairs. Ears brown (paler than dorsal pelage); relatively short (reaching ca. half-way along muzzle when laid forward); inner margins joined by interaural band with V-shaped fold in middle (Baeten *et al.* 1984). Tragus small, hatchet-shaped with bend in posterior margin and tip pointed; concealed by antitragus. Antitragus large, nearly semi-circular with upper margin pale and thick. Posterior side of interaural band supporting inconspicuous crest of slightly longer (3.5–4 mm) and slightly coarser black hairs. No gular gland. Wings semi-translucent, blackish-brown to pale grey (depending on amount of blackish-brown pigmentation); interfemoral membrane dark brown dorsally, whitish ventrally. First phalanx of third finger 19.4 (19–21) mm, n = 17; first phalanx of fourth finger: 15.4 (15–17) mm, n = 10 (cf. *T. demonstrator*, *T. condylura*).

Skull not extremely dorsoventrally flattened. Anterior of braincase not noticeably elevated above plane of rostrum. Sagittal crest only moderately developed (both anteriorly and posteriorly);

lambdoid crest weakly to well developed, forming a low to moderate helmet in ♀♀ and a moderate to well-developed helmet in ♂♂. Anterior palatal emargination closed; incisive foramina visible (Figure 100a). Basisphenoid pits moderate in depth, medium to large, their width ranging from equal to almost twice their distance apart. Anterior upper premolar distinctly shorter than cingulum of posterior premolar, within toothrow or slightly displaced labially; canine and posterior premolar separated or in contact. M³ with third ridge absent. Two lower incisors on each side, bicuspid, crowded. Lower canines with cingula not greatly enlarged, sometimes almost in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band, M³ with third ridge present (but usually* < half length of second ridge) or absent; anterior palatal emargination closed; FA: > 40 mm. *In *T. condylura*, the length of the third ridge is variable and can be up to half length of second ridge.

Tadarida condylura. Ventral pelage with little or no white areas; ventral flank-stripe white. Crown and neck same colour as back. First phalanx of fourth finger almost always longer (18.3 [17–20] mm). Neonates dark. Skull with sagittal crest usually well developed. Basisphenoid pits shallow, small. M³ with third ridge present (but usually < half length of second ridge).

T. congica. Larger and heavier (FA: 54–58 mm; WT: 42–64 g). Ventral pelage not mainly white or cream.

T. demonstrator. First phalanx of third finger almost always longer (17.7 [16–19] mm). Males with pair of glands between penis and anus. Wings medium to dark grey. Basisphenoid pits deep.

T. midas. Much larger and heavier (FA: 59–67 mm; WT: 38–69 g).

T. trevori. Forearm longer (51–55 mm). Ventral pelage pale but not mostly white or cream. Skull with basisphenoid pits deep and large.

Distribution Endemic to Africa. Only known from Southern Rainforest–Savanna Mosaic and Zambeian Woodland BZ. Recorded from Rwanda, Burundi, DR Congo, SW Tanzania, C Angola, Zambia and W Mozambique (Harrison 1968, Smithers & Lobão Tello 1976, Ansell 1978, Baeten *et al.* 1984, Van Cakenberghe *et al.* 1999). Gaps in the distribution, especially in E Angola, might reflect insufficient collecting.

*Tadarida niveiventer*

Habitat Poorly known. In south-central Africa, found in wetter woodland savannas, particularly miombo woodland. The presence of suitable day-roosts in tall miombo woodland may be an important determinant of their occurrence.

Abundance Uncertain. Less commonly mist-netted than *T. condylura* at Kikwit, DR Congo (Van Cakenberghe *et al.* 1999), at Nyamata and Rukira in Rwanda (Baeten *et al.* 1984) and in W Zambia (Cotterill 2002b).

Remarks In the Ikkelenge Pedicle, NW Zambia, a colony of seven adults (one ♂ and six ♀♀) roosted high up in a hollow tree *Brachystegia* sp. (Cotterill 2002b). Colonies have also been found in attics and in cracks in walls of buildings (Ansell 1967). Litter-size

(Zambia): one (n = 7). Reproductive chronology not known. In W Zambia, pregnant ♀♀ (near full-term) were recorded in Oct 1990 and Nov 1998; 4 of 6 ♀♀ had well-developed fetuses in Jan 1952, and lactating ♀♀ and/or juveniles have been collected in Jan, Feb and Mar (Ansell 1967, Cotterill 2000, 2002b). Although this limited evidence suggests births from ca. Nov to Feb (hot-wet season) as in *T. condylura* in Malawi (Happold & Happold 1989b), it is not known if the ♀♀ are monoestrous or polyoestrous, and there are no data for other months. Ectoparasites include mites *Spinturnix semilunaris* (Acari: Spinturnicidae) and *Chelanyssus aethiopicus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Tadarida petersoni PETERSON'S FREE-TAILED BAT

Fr. Tadaride de Peterson; Ger. Petersons Bulldoggfledermaus

Tadarida petersoni El-Rayah, 1981. R. Ontario Mus. Life Sci. Occas. Pap. 36: 3. 15 km S Kumba (04° 39' N, 09° 26' E), Cameroon.

Taxonomy Subgenus *Xiphonycteris*. Synonyms: none. Chromosome number (Cameroon): 2n = 48; aFN = 54; one pair large and three pairs medium metacentric and 19 pairs medium-small acrocentric autosomes (Smith *et al.* 1986).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 32–35 mm); ears joined by interaural band; M³ with third ridge present but < half length of second ridge; anterior palatal emargination narrow; wings blackish-brown; ventral pelage pale, no ventral flank-stripe in contrasting colour; canines without enlarged cingula. Sexes similar in colour; ♂♂ on average slightly larger than ♀♀. Pelage

short, sparse; covering rump but not extending onto interfemoral membrane. Dorsal pelage dark sepia brown; no grizzling, no spots; hairs with pale brown at base and sometimes with whitish tip. Ventral pelage pale brown to dark beige becoming paler mid-ventrally; no mid-ventral markings, no ventral flank-stripe in contrasting colour. Head not extremely flattened. Upper lip with five well-defined wrinkles and many spoon-hairs. Ears blackish-brown; relatively small (not reaching snout by 2–3 mm when laid forward); inner margins joined on muzzle by an interaural band with a forward-projecting knob-like protuberance (containing a backward-opening interaural pocket). Tragus small, subrectangular, concealed by antitragus. Antitragus large, roughly rectangular. No interaural crest. Wings and interfemoral membrane blackish-brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase prominently elevated above plane of rostrum (Figure 99b). Sagittal crest low, lambdoid crest low, occipital helmet slight. Anterior palatal emargination narrow. Basisphenoid pits moderate in depth, small, their width much less than their distance apart. Upper incisor not procumbent. Upper canine with cingula not greatly enlarged; viewed laterally, incisor not obscured by canine (cf. *T. spurrelli*). Anterior upper premolar slightly taller than cingulum of posterior premolar, within tooththrow; canine and posterior premolar well separated. M³ with third ridge present but < half length of second ridge. Two lower incisors on each side; small, bicuspid and crowded. Lower canines unmodified; cingula not greatly enlarged and not in contact. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge absent or present but < half length of second; anterior palatal emargination narrow; FA almost always < 40 mm (Table 20, p. 488):

T. brachyptera. Usually larger (FA: 35–38 mm; GLS: 16.2–19.9 mm).

Skull with lambdoid crest very well developed.

T. nanula. Forearm shorter (27–31 mm). M³ with third ridge absent.

Basisphenoid pits shallow, smaller and further apart.

T. spurrelli. Forearm shorter (27–30 mm). M³ with third ridge absent.

Upper and lower canines with greatly enlarged cingula, especially in ♂♂; in lateral view, upper incisor obscured by canine. Usually one minute lower incisor on each side. Braincase lower but occipital helmet prominent, especially in ♂♂. Basisphenoid pits shallow.

T. thersites. Forearm usually longer (35–42 mm).

T. bakarii. See in profile of *T. brachyptera*.

Distribution Endemic to Africa. Known only from Rainforest BZ, at one locality in Ghana and five in Cameroon (El-Rayah 1981, Smith *et al.* 1986), but likely to occur elsewhere in the Rainforest BZ where suitable habitat exists, and likely to extend into the Northern Rainforest–Savanna Mosaic. A specimen from Sierra Leone, formerly identified as *T. petersoni* and referred to by Koopman (1989), is now considered to represent *T. brachyptera* (Grubb *et al.* 1998).

Habitat At most localities from which *T. petersoni* has been recorded up until now, the rainforest has been modified by forestry and agriculture and is more open than the undisturbed or climax forests found in less populated areas nearer the Equator (ROM, El-Rayah 1981). Other specimens (AMNH) appear to have been collected in or near the invasive Guinea woodland savanna (El-Rayah 1981). Has been recorded sympatrically with *T. spurrelli*, *T. thersites* and *T. brachyptera*.

Abundance Uncertain.

Tadarida petersoni

Remarks Apparently nothing else is known about the habits of this species.

Conservation IUCN Category: Near Threatened.

Close to qualifying as Vulnerable. Population trend not known, but recorded from only two locations in highly fragmented habitats undergoing further degradation as a result of shifting agriculture and small- and large-scale extraction of wood.

Tadarida pumila LITTLE FREE-TAILED BAT

Fr. Petite tadaride; Ger. Kleine Bulldoggfledermaus

Tadarida pumila (Cretzschmar, 1830–1831). In: Rüppell, Atlas Reise Nordl. Afr., Zool. Säugeth. 1: 69. Massawa, Eritrea.

Taxonomy Originally *Dysopes pumilus*. Synonyms: *cristatus*, *elphicki*, *faini*, *frater*, *gambianus*, *hindei*, *langi*, *leucogaster*, *limbata*, *naivashae*, *nigri*, *pusillus*, *websteri*. Contains dark- and light-winged forms, and possibly contains several species (for details see Meester *et al.* 1986). Peterson *et al.* (1995) consider *leucogaster* (including *cristatus*, *nigri* and *websteri*), *naivashae* and *limbata* to be distinct species: Goodman (2011) also considers *leucogaster* to be distinct. Taylor (1999b) suggests there is a cryptic species in South Africa and Swaziland. However, Jacobs *et al.* (2004) concluded, on the basis of genetic similarity between phenotypically diverse specimens (including both pale- and dark-winged forms), that there is no evidence of cryptic species in southern Africa. Pending revision, we retain the forms listed above as synonyms of *T. pumila* but warn that diversity and discrepancies in the information given below (and in literature) might reflect the presence of several species. Subspecies: pending revision, recognition of subspecies is not useful. Chromosome number (Uganda, Cameroon, Somalia): 2n = 48; aFN = 58; one pair large metacentric, two pairs medium metacentric, three pairs medium subtelocentric and 17 pairs acrocentric (Dulić & Mutere 1973b, Smith *et al.* 1986). In contrast, Rautenbach *et al.* (1993) reported aFN = 66 and ten pairs of biarmed autosomes in specimens from Namibia and South Africa.

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 32–39 mm); ears joined by interaural band; M³ with third ridge > half length of second ridge; wings white or dark; ventral flank-stripe white, off-white or absent; dorsal pelage not pale brown; ♂♂ with short, unicoloured interaural crest. Sexes almost similar. Pelage velvety, sometimes oily, covering rump but not extending onto interfemoral membrane; mid-dorsal hairs 3–4 mm. Dorsal pelage almost black, brown, greyish-brown or reddish-brown, no grizzling, no white flecks or spots; hairs with paler base. Ventral pelage similar or paler; mid-ventral markings very variable or absent; ventral flank-stripe white, off-white or absent. Head not extremely flattened. Upper lip with 5–7 well-defined wrinkles (Kenya, Malawi), or > 7 (Freeman 1981), and many spoon-hairs. Ears black or dark brown; comparatively small (not reaching snout when laid forward), inner margins joined by interaural band with a backward-opening pocket-like invagination in middle, not separated as erroneously reported by Bouchard (1998). Tragus very small, squarish or sometimes with small lobe at top of posterior margin; concealed by antitragus. Antitragus much larger than tragus, roughly semi-circular. Adult ♂♂ with interaural crest of short, brown hairs (osmetrichia) arising from the interaural pocket. No gular gland. Wings with white or blackish-brown pigmentation (intermediate forms in some localities), and often semi-translucent. Interfemoral membrane blackish-brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum (Figure 99f). Sagittal crest moderate anteriorly, low or absent posteriorly; lambdoid crest poorly to moderately developed. Anterior palatal emargination variable:

can be (a) closed and separated from incisive foramina by bony bar, (b) narrow but still separated from incisive foramina (Figure 100b) or (c) narrow and not separated from the incisive foramina, which retain only a remnant of the bony septa between them (Figure 100c). Basisphenoid pits moderate in depth and medium-sized (their width ≥ their distance apart), or shallow and small (their width much less than their distance apart) as, for example, in *leucogaster* (Peterson *et al.* 1995). Anterior upper premolar ca. same height as cingulum of posterior premolar or shorter, within toothrow or displaced labially; canine and posterior premolar separated or in contact. M³ with third ridge nearly as long as second. M³–M³ 45.5 (44–48)% of GLS, n = 27 (cf. *T. chapini*). One or two lower incisors on each side, small, bicuspid, crowded. Lower canines slender and relatively short, cingula not greatly enlarged and not in contact. Dental formula: $\frac{1^{123}}{2^{123}} = 30$ or $\frac{1^{123}}{1^{123}} = 28$.

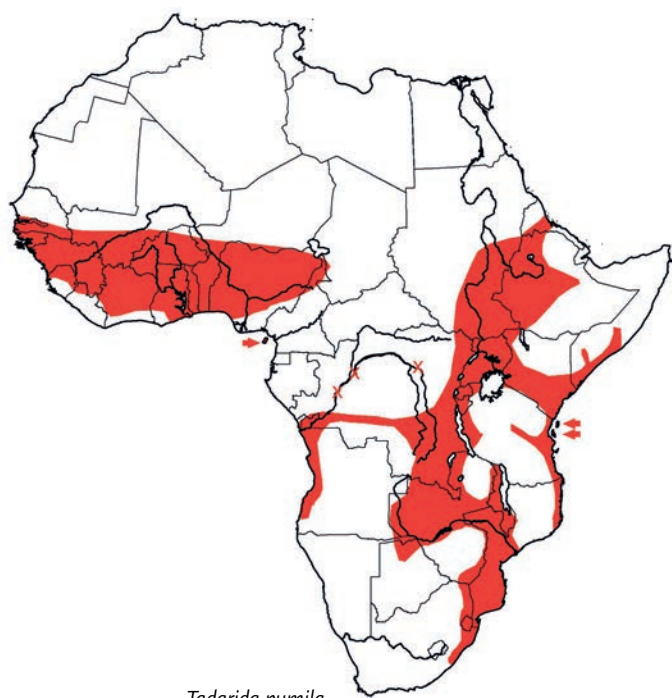

Geographic Variation *Tadarida pumila* currently includes forms with white wings, white ventral flank-stripe and pale mid-ventral markings (sometimes referred to as *T. limbata*), and forms with uniformly dark pelage and dark wings. These forms have identical cranial and dental characters and, in Uganda and DR Congo, dark and pale forms, and every intermediate form, exist sympatrically, which suggests a high degree of colour polymorphism. Alternatively, perhaps there might be two or more species that hybridize, given some circumstance(s), when sympatric. This variation in colour calls for investigation.

Similar Species Only one other African *Tadarida* has the following combination of characters: ears joined by interaural band; M³ with third ridge > half length of second; no paired tail-glands at base of tail; FA: <40 mm (Table 20, p. 488):

Tadarida chapini. Dorsal pelage pale brown; arm-wing yellowish-white with black specks; ♂♂ with long bicoloured interaural crest. M³–M³ relatively narrower (42.7 [41–44]% of GLS, n = 11).

Distribution Widespread south of the Sahara. Most often recorded in the Sudan Savanna and Guinea Savanna BZs, Rainforest–Savanna Mosaics, Coastal Forest Mosaic BZ and Zambezian Woodland BZ, but there are a few records in Rainforest BZ. Recorded, disjunctly, from Senegal to Eritrea, Ethiopia and Somalia, and south-westwards and southwards to Angola, Botswana and KwaZulu–Natal, South Africa. Also Bioko I., Pemba I. and Zanzibar I. Extraliminally: Yemen, Madagascar, Aldabra I. Records from Cape Province, South Africa, have been re-identified as *Sauromys petrophilus* (Jacobs & Fenton 2001). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Mainly savannas including undifferentiated woodlands, *Isoblerlinia* woodland, mosaic of lowland rainforest and secondary grassland (Guinea savanna), wetter and drier miombo woodlands, coastal mosaics, *Acacia–Commiphora* bushland and thicket, and

Tadarida pumila

other thicket bushlands. Seldom recorded in West African lowland rainforest, but found in swampy gallery forests in DR Congo. Not found in montane areas except possibly in Ethiopia; not found above 1000 m south of ca. 10° S. Probably absent in arid areas except near rivers. Not dependent on rocky, hilly or mountainous terrain for its roosts.

Abundance Common to very common throughout geographic range, especially in built-up areas where buildings provide abundant day-roosts.

Adaptations Aspect ratio high; wing-loading medium. Flight fast, agile with very poor manoeuvrability; turns by banking (radius of turn >1.7 m) but not by stalling-and-twisting; cannot hover, cannot take off from ground, must dive at least 1.5 m to gain sufficient speed for flight; must swoop upwards to reduce speed prior to landing. Unable to fly in a 1×1×1 m enclosure. Scuttling and climbing are fast and very efficient, forwards and backwards. Often roosts by day under corrugated iron roofs; temperatures 17–39°C and relative humidities 39–94% were recorded where bats roosted in Uganda (Mutere 1969). Also roosts in hollow trees and palms, gaps in thatch and narrow cracks in tree trunks and brickwork; not known to roost in caves. In Kruger N. P., South Africa, 'found in rocky environments with an abundance of crevices in which colonies can take refuge in large numbers' (Pienaar *et al.* 1987 as quoted by Bouchard 1998), but this comment is ambiguous and also there are no other records of *T. pumila* roosting in lithophilic day-roosts – therefore this habit needs confirmation. Because it is necessary to dive to gain the requisite speed for flight, entrances are always at least 1.5 m above ground; landing-sites are often stained; bats often scuttle several metres from landing-sites to roost-sites. This species clings or crouches in contact against both horizontal and sloping surfaces, and prefers to tuck into small nooks and crannies into which it scuttles backwards using tactile hairs on rump and feet (and probably tail) for guidance.

Emerges soon after dusk (earlier in overcast weather than on clear or moonlit nights); harem ♂♂ emerge first (McWilliam 1989). Roost-fidelity variable. Of 350 bats released 43 km from their day-roost, 16% returned within one night (some within one hour) and others returned subsequently (Mutere 1969). Sometimes roosts with *T. condylura*. Becomes torpid during day at temperatures below 24 °C. Predicted mean maximum urine concentration is comparatively low (3251 mOsmol/kg); non-flying captive bats (including a lactating ♀) fed on flying-termites did not drink but, because evaporative water loss is very high during flight, independence of drinking water in the wild is highly unlikely (Happold & Happold 1988). Further information in Bouchard (1998).

Foraging and Food Forages by fast-hawking high above tree canopies, over clearings and open water, and sometimes between well-spaced tree trunks and along fairly open waterways. Combines circling (often gaining height) with long straight flights; and swerves and dives in pursuit of prey. Often seen foraging ca. 50–70 m above ground, and sometimes within 2–3 m of open ground. Foraging occurs throughout night, with maximum activity during first hour of darkness and between 04:00 and 05:00h (Mutere 1969). Captive adults, while scuttling around their cages, find and eat live and dead insects, and Marshall & Corbet (1959) found cockroaches in stomachs of non-volant juveniles (but not adults): this suggests opportunistic foraging by chasing but perhaps only in the day-roosts. Subsequently, Aspöberger *et al.* (2003) observed that cockroaches comprised more than 60% of the diet of *T. pumila* at Amani N. R., Tanzania; cockroaches shared the roost of these bats and it was suggested that the bats chased this prey in the roost and probably used vision to do so. Adults feed opportunistically, mainly on soft-bodied insects; diet includes Lepidoptera, Diptera, Coleoptera, Hymenoptera, Hemiptera, Orthoptera, Neuroptera and others (Whitaker & Mumford 1978). Probably does cotton growers much good by feeding on Cotton Bollworm moths (R. C. Wood in Kershaw 1922).

Echolocation Search-phase calls (Malawi) are mostly (90–100%) shallow linear FM sweeps (cf. 7–30% in *T. condylura*) with start-frequencies in the range 21–31 kHz and end-frequencies 20–27 kHz, call-duration 13–20 ms (five light-tagged bats foraging high above ground; M. Happold unpubl.). Sequences of shallow linear FM calls are occasionally punctuated by one or more shallow sigmoid or shallow quasi-linear FM sweeps, but regular alternation between calls of different frequencies (as in *T. condylura*) has not been recorded. In cluttered environments (near day-roosts or ground) *T. pumila* emits steep linear FM sweeps with start-frequencies 28–50 kHz and end-frequencies 19–38 kHz, and there is a gradual transition to narrow bandwidth calls as the bat flies into open spaces (12 bats, as released). Similarly, there is a gradual transition from narrow bandwidth search-phase calls to broad bandwidth calls as prey is approached (Figure 96i–l). In South Africa, calls emitted by three individuals flying in open were shallow FM with similar frequencies (Taylor 1999a).

Social and Reproductive Behaviour Forages singly but roosts in groups of ca. five to several hundreds of individuals. The social organization of a population in Ghana was based on female-defence polygyny (harem formation) with elements of resource-defence polygyny (McWilliam 1988b). Harems comprised an adult ♂ with

up to 21 adult ♀♀ and their young; composition stable during a 16-month study; heaviest ♂♂ had largest harems. Harems roosted in separate day-roosts; roost-fidelity very high. Some young ♀♀ were recruited into their natal harems, thereby replacing annual loss of harem ♀♀ and suggesting harem ♀♀ might often be related, but most young dispersed. In contrast, one day-roost in Malawi contained 20–30 individuals at any one time during a nine-month study, but the composition of the colony was labile and the ratio of adult ♂♂ to ♀♀ in monthly captures of bats emerging at dusk was 1 : 3.7 (n = 71) (Happold & Happold 1989b). Furthermore, a captive group (4 ♂♂, 6 ♀♀) from South Africa roosted in clusters that often included more than one ♂, and the dominant ♂ did not exclude subordinate ♂♂ from access to clusters of ♀♀, suggesting that these bats did not form harems (Somers & Bouchard 2000). Possibly, these studies were on different species.

Reproduction and Population Structure Litter-size: normally one throughout geographic range, very rarely two. Implantation usually in right horn. Reproductive chronology seasonal multimodal polyoestry, sometimes with postpartum oestrus, and potentially up to five litters/year although two or three are the norm in most localities. Gestation ca. 60 days (Malawi and South Africa), 67–72 days (N Ghana); reproductive delays not known to occur. The number of litters/year, the timing of births and the first oestrus after parturition vary with latitude and rainfall. At 9–10° N (Mole N. P., N Ghana), there are three consecutive, synchronized births (at least two followed by postpartum oestrus) during the wet season May–Oct and, for at least some ♀♀, two more births with postpartum oestrus in the dry season. Data from Niger, Burkina, Nigeria and Sudan are consistent with this boreal cycle. At 0–1° N in Uganda, there appear to be three peaks in births at 4-month intervals with less synchrony and without postpartum oestrus. At 02° 18' S (Masalani, near Kibwezi, Kenya) one litter is born in each of the two wet seasons (Nov and Mar–Apr); no postpartum oestrus. At 15° 16' S in Malawi and 25° S in South Africa, most ♀♀ have three litters during the wet season (Nov–Mar), with postpartum oestrus after births 1 and 2, and occasionally after birth 3. (References: Mutere 1973a, McWilliam 1976, 1987c, O'Shea & Vaughan 1980, van der Merwe *et al.* 1986, 1987, Happold & Happold 1989b, Monadjem 1998b).

Neonates are naked except for long tactile hairs, and are ca. 33% adult weight and 56% adult total length; eyes and auditory meatus closed (Happold & Happold 1989b). Growth rate, and attainment of sexual maturity, vary geographically. In Ghana, growth rate is very rapid; young reach 85% of adult-size and 75% of adult-weight

and become volant by ca. 19 days; are weaned between 21–28 days; attain adult-size and adult-weight at ca. three months; attain sexual maturity at ca. three months in ♀♀, and ca. five months in ♂♂ (McWilliam 1976, 1987c). In Malawi and southern Africa, ♀♀ attain sexual maturity in the breeding season following their birth.

Predators, Parasites and Diseases Emerging bats are commonly taken by Bat Hawks, *Macheiramphus alcinus*; and are also taken by other raptors *Accipiter tachiro* (1–5 bats/bird/night), *Falco subbuteo*, *Milvus migrans* and *Aquila wahlbergi* (McWilliam 1989, Rautenbach *et al.* 1990, Fenton *et al.* 1994). Ectoparasites include six species of bed-bugs and their allies (Hemiptera: Cimicidae, Polyctenidae); seven species of fleas (Siphonaptera: Ischnopsyllidae); four species of bat-flies (Diptera: Nycteribiidae, Streblidae), a tick *Lepidixodes kopsteini* (Acari: Ixodidae) and 13 species of mites (Acari: Laelapidae, Spinturnicidae, Macronyssidae, Myobiidae, Trombiculidae, Ereynetidae, Chirodiscidae, Sarcoptidae) (Anciaux de Faveaux 1984). Viruses isolated from *T. pumila* include Chikungunya, Dakar Bat, Yellow Fever, West Nile and Zika viruses, and others (such as Bukalassa Bat and Entebbe Bat viruses), which are not known to cause illness in humans (Anciaux de Faveaux 1984, C. Calisher pers. comm.).

Conservation IUCN Category: Least Concern.

Tadarida russata RUSSET FREE-TAILED BAT

Fr. Tadaride roussâtre; Ger. Rostfarbene Bulldoggfledermaus

Tadarida russata (J. A. Allen, 1917). Bull. Am. Mus. Nat. Hist. 37: 458. Medje, Orientale, DR Congo.

Taxonomy Originally *Chaerephon russatus*. Synonyms: none. Considered closely related to *T. aloysiisabaudiae* (Fenton & Peterson 1972). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral

membrane; medium-sized for an African molossid (FA: 42–46 mm); ears joined by interaural band; M³ with third ridge > half length of second ridge, anterior emargination closed; wings mostly dark brown; ventral pelage moderately dark; no ventral flank-stripe in contrasting colour; no tail-glands. Sexes almost similar. Pelage short (mid-dorsal hairs 3–4 mm), nape nearly naked. Dorsal pelage dark rusty-brown to sepia

brown; sometimes with single, whitish hairs or small pale spots; dorsal hairs with paler base. Ventral pelage slightly paler and greyer, sometimes becoming even paler mid-ventrally; no mid-ventral markings, ventral flank-stripe same colour as flanks. Head not extremely flattened. Upper lip with 7–8 well-defined wrinkles on each side and many spoon-hairs. Ears blackish-brown; of medium relative length (reaching snout when laid forward); inner margins joined across forehead by an interaural band with a forward-projecting knob-like protuberance containing a backward-opening interaural pocket. Tragus minute, narrow, concealed by antitragus. Antitragus small, rounded. Interaural crest of short black hairs arising from interaural pocket of ♂♂. Gular gland absent. Wings dark brown from body to fourth finger, outer part semi-translucent and paler. Interfemoral membrane brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum. Sagittal crest low or absent; lambdoid crest moderate. Anterior palatal emargination closed; incisive foramina visible. Basisphenoid pits moderate in depth, large, their width more than twice their distance apart. Anterior upper premolar rising distinctly above cingulum of posterior premolar, within toothrow; canine and posterior premolar well separated. M^3 with third ridge just over half length of second. Two lower incisors on each side; minute, bicuspid and not crowded. Lower canines with cingula not greatly enlarged, well separated. Canines of ♂♂ on average larger than those of ♀♀. Anterior lower premolar larger in ♂♂ than in ♀♀. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation Three specimens from Kenya are larger than three from Cameroon with which they were compared, suggesting that the Kenyan population may prove significantly larger and worthy of subspecific recognition (Schlitter *et al.* 1986).

Similar Species Four other African *Tadarida* have the following combination of characters: M^3 with third ridge > half length of second; wings neither white nor whitish; no ventral flank-stripe in contrasting colour; no tail-glands (Table 20, p. 488):

Tadarida aloysiisabaudiae. Larger (FA: 48–53 mm; GLS: 20.0–22.3 mm; GWS: 11.7–13.1 mm). Otherwise very similar in pelage pattern and colour as well as in external characters.

T. ansorgei. Dorsal pelage dark greyish-brown to chocolate brown or reddish-brown, somewhat frosted, occasionally with white spots; hairs with paler tips. Skull with anterior of braincase not noticeably elevated above plane of rostrum. Anterior palatal emargination narrow (bulb-shaped). Basisphenoid pits moderate in depth, small, their width less than their distance apart.

T. bivittata. Larger (FA: 46–51 mm; GLS: 19.5–21.3 mm). Skull with anterior palatal emargination narrow (bulb-shaped). Basisphenoid pits moderate in depth, small, their width ≤ their distance apart.

T. pumila (sometimes). Smaller (FA: 32–39 mm; GLS: 14.2–17.6 mm). Skull with basisphenoid pits moderate in depth, small, their width ≤ their distance apart.

Distribution Endemic to Africa. Currently only known from four widely separated areas in Rainforest BZ; in SW Côte d'Ivoire (J. Fahr pers. comm.), Ghana, Cameroon and NE DR Congo (Allen 1917a, Fenton & Peterson 1972), and unexpectedly from Somalia–Masai Bushland BZ at Hell's Gate in Kenya (Schlitter *et al.* 1986).

Tadarida russata

Habitat Recorded along edge of Rainforest BZ in the belt of invasive Guinea woodland (type 11a of White 1983), which extends from NE DR Congo to Ghana and further westwards to Guinea (Fenton & Peterson 1972). Sympatric with *T. spurrelli* and *T. thesites*. Also recorded from Hell's Gate Canyon in the mosaic of East African evergreen bushland and secondary *Acacia* wooded grassland (type 45 of White 1983) in Kenya (Schlitter *et al.* 1986).

Abundance Uncertain; very rarely recorded.

Remarks Twenty-seven (4 ♂♂, 20 ♀♀, 3 not adult) were taken at Medje, DR Congo, on 8 Sep 1910, when a huge hollow tree housing a large colony of *T. russata* and *T. congica* fell during a storm (Lang & Chapin 1917b). No further specimens were obtained until 1970 when five were taken in Cameroon (Peterson 1971a), one in Ghana in 1971 (Fenton & Peterson 1972) and three in Kenya in 1985 (Schlitter *et al.* 1986). The Cameroon specimens were mist-netted over a river and forest streams. In captivity, the *T. russata* from Medje huddled together up to six deep, and regrouped with much squeaking and fighting if disturbed. They scuttled and climbed with speed and agility (as typical of *Tadarida*). Six of the 20 ♀♀ captured were pregnant, each with one embryo. Bat flies (Nycteribiidae) were found in the bats' pelage. A flea, *Lagaropsylla senckenbergiana* (Siphonaptera: Ischnopsyllidae) was found on *T. russata* from Côte d'Ivoire (Beaucournu & Fahr 2003).

Conservation IUCN Category: Data Deficient.

Population trend not known, but the known records are in threatened habitats (highly threatened in West Africa) and it appears to be rare throughout its geographic range. Major threats: extraction of wood (subsistence, selective logging and clear-cutting).

Tadarida spurrelli SPURRELL'S FREE-TAILED BAT

Fr. Tadaride de Spurrell; Ger. Spurrells Bulldoggfledermaus

Tadarida spurrelli (Dollman, 1911). Ann. Mag. Nat. Hist. ser. 8, 7: 211. Bibianaha, Ghana.

Taxonomy Originally *Xiphonycteris spurrelli*. Subgenus *Xiphonycteris*. Probably closely related to *T. nanula*. Synonyms: none. Chromosome number (Cameroon): 2n = 48; aFN = 64; one pair large metacentric, three pairs small metacentric, four pairs medium subtelocentric, one pair small subtelocentric and 14 pairs medium-small acrocentric autosomes (Smith *et al.* 1986).

Description Very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; one of the two smallest African *Tadarida* (FA: 27–30 mm); ears joined by interaural band; M³ with third ridge absent; anterior palatal emargination narrow; wings blackish; ventral pelage mostly pale; no ventral flank-stripe in contrasting colour; usually only one lower incisor on each side; canines with greatly enlarged cingula especially in ♂♂. Females not easily distinguished from *T. nanula*. Sexes similar in colour; some morphological differences; ♀♀ smaller on average than ♂♂, especially craniodentally. Pelage short (mid-dorsal hairs 2–3 mm). Dorsal pelage uniformly dark reddish-brown, sometimes with scattered white hairs and (possibly only in ♂♂) scattered dark brown hairs, but no flecks or spots; hairs mostly reddish-brown with whitish base. Ventral pelage white merging into greyish-white on chest and throat and into brown on flanks; apparently no mid-ventral markings; ventral flank-stripe same colour as flanks. Head not extremely flattened. Upper lip with 6–7 well-defined wrinkles on each side and few spoon-hairs. Ears blackish-brown, relatively small (not reaching snout when laid forward); inner margins joined by interaural band with forward- and downward-pointing V-shaped fold in middle. Tragus minute, concealed by antitragus. Antitragus large, tall, with rounded top and broad base. In ♂♂, interaural band has darker and longer hairs on the posterior margin, but no distinct crest; no information for ♀♀. Wings and interfemoral membrane blackish.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum (Freeman 1981). Sagittal crest moderate; lambdoid crest very well developed, especially in ♂♂; helmet prominent, especially in ♂♂. Anterior palatal emargination narrow, sometimes somewhat bulb-shaped (narrowest between incisors). Basisphenoid pits shallow, small, their width < distance apart (sometimes half their distance apart). Upper incisors and canines almost in same plane. Upper incisors widely separated at their bases, and with cutting edges apically sharper than in *T. nanula* (El-Rayah 1980). Upper canines with enlarged cingula, especially in ♂♂: when

viewed laterally, upper incisor obscured by the canine cingulum in ♂♂ (Figure 104b) (cf. *T. nanula*), but partly visible in ♀♀. Anterior upper premolar distinctly taller than cingulum of posterior premolar and within toothrow in ♂♂, smaller and slightly displaced lingually in ♀♀; canine and posterior premolar separated. M³ with third ridge absent. Usually one lower incisor on each side, bicuspid and minute, but occasionally the outer incisor is retained in both sexes (Koopman 1989). Lower canines (Figure 105b) also large with greatly enlarged cingula (especially in ♂♂); in ♂♂ (and some ♀♀), the cingula meet centrally and form an arch over the minute incisors (cf. *T. nanula*) (Rosevear 1965, De Vree 1969, Kock 1969b). In ♂♂, the first lower premolar is larger at base than the second, whereas in ♀♀ the first is smaller than the second (De Vree 1969, El-Rayah 1980). Dental formula: usually $^{1123}/_{1123} = 28$, occasionally $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge absent or present but < half length of second; palatal emargination narrow; FA almost always < 40 mm (Table 20, p. 488):

Tadarida brachyptera. Forearm longer (34–41 mm). M³ with third ridge present but < half length of second. Lower canines without greatly enlarged cingula.

T. nanula. Wing-membranes semi-translucent, sometimes brownish, sometimes with light to moderate white pigmentation. Upper canines without enlarged cingula; when viewed laterally, upper incisors are visible – not hidden by the canine cingula. Cingula of lower canines not greatly enlarged and never in contact (cf. in contact in adult ♂♂ and some ♀♀ in *T. spurrelli*). Usually two lower incisors on each side.

T. petersoni. Forearm longer (32–35 mm). M³ with third ridge present but < half length of second ridge. Upper and lower canines without enlarged cingula. Usually two lower incisors on each side. Skull with braincase higher but occipital helmet poorly developed. Basisphenoid pits moderate in depth.

T. thersites. Forearm much longer (35–42 mm). Ventral pelage very dark. Lower canines without greatly enlarged cingula. Two lower incisors on each side.

T. bakarii. See in profile of *T. brachyptera*.

Tadarida spurrelli

Distribution Endemic to Africa. Recorded disjunctly from Rainforest BZ and Rainforest–Savanna Mosaics, from Sierra Leone, Liberia, Guinea, Côte d'Ivoire, Ghana, Togo, Cameroon, perhaps Central African Republic, Equatorial Guinea including Bioko I. and NE DR Congo (De Vree 1969, Kock 1969b, Jones 1971, El-Rayah 1981, Schlitter *et al.* 1982, Smith *et al.* 1986, Koopman 1989, Juste & Ibáñez 1994, Koopman *et al.* 1995, Grubb *et al.* 1998, RMCA). The lack of records from most of the Congolian rainforest in DR Congo might reflect insufficient collecting.

Habitat Found in wetter and drier types of lowland rainforest, secondary forest and areas of invasive Guinea woodland savanna

close to the rainforest. Has been recorded along streams and rivers (e.g. Schlitter *et al.* 1982, Juste & Ibáñez 1994).

Abundance Uncertain; considered rare but possibly more common and widespread than records indicate. Seems to be the most common molossid on Bioko I. (Juste & Ibáñez 1994).

Remarks Nothing else appears to be known about this species.

Conservation IUCN Category: Least Concern.

Tadarida teniotis EUROPEAN FREE-TAILED BAT

Fr. Tadaride de Cestoni; Ger. Europäische Bulldoggfledermaus

Tadarida teniotis (Rafinesque, 1814). Précis. Som., p. 12. Sicily, Italy.

Taxonomy Originally *Cephalotes teniotis*. Subgenus *Tadarida*. Synonyms: *cestoni*, *nigrogriseus*, *savii*, *rueppelli* (see Simmons 2005), but only *rueppelli* and *teniotis* occur in Africa. Subspecies: two, both in Africa. Chromosome number (Croatia): 2n = 48; aFN = 76 (Dulić & Mrakovčić 1980).

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; large for an African molossid; ears relatively large, meeting to form a V-shaped valley; wings blackish; no ventral flank-stripe in contrasting colour; three lower incisors on each side (cf. two in other *Tadarida*); M³ with third ridge = second ridge. Sexes similar in colour; ♀♀ on average with larger body dimensions. Pelage fine, soft, dense; mid-dorsal hairs ca. 7 mm. Dorsal pelage ashy-grey or brownish-grey; no spots, flecking or frosting; hairs grey

with whitish base. Ventral pelage paler; no mid-ventral markings; no ventral flank-stripe in contrasting colour. No orange-phase. Head not extremely flattened. Upper lip with four well-defined wrinkles on each side and comparatively few spoon-hairs. Ears blackish, relatively large (extending well beyond snout when laid forward); inner margins only just meeting on forehead to form V-shaped valley. Tragus short, concealed by antitragus. Antitragus large, subrectangular. No interaural crest. No gular gland. Wings and interfemoral membrane blackish. Ventral sides of forearms and legs naked and blackish. Foot with raised pad on sole (plantar pad).

Skull not extremely dorsoventrally flattened. Anterior of braincase not elevated above plane of rostrum. Sagittal crest absent or weakly developed; lambdoid crest poorly to moderately developed. Anterior palatal emargination wide. Interdental palate broad, narrowing only very slightly towards canines, not constricted at level of posterior

premolar. Basisphenoid pits moderate in depth, large, their width greater than their distance apart. Anterior upper premolar rising distinctly above level of cingulum of posterior premolar, within toothrow; canine and posterior premolar well separated. M^3 with third ridge equal in length to second. Three lower incisors on each side (cf. two in all other African species in subgenus *Tadarida*), bicuspid, crowded. Lower canines with cingula not greatly enlarged and not in contact. Dental formula: $^{1123}/_{3123} = 32$.

Geographic Variation Two subspecies are currently recognized (Simmons 2005):

T. t. teniotis: Morocco to Libya (and extraliminally Canary Is., W Mediterranean Europe to Central Asia). Dorsal pelage brownish-grey.

T. t. rueppelli: Egypt (and extraliminally Arabia *sensu* Harrison & Bates 1991). Dorsal pelage paler, ashy-grey.

Similar Species Four other *Tadarida* in Africa have ears with inner margins meeting, or almost meeting, to form a V-shaped valley:

Tadarida aegyptiaca. Two lower incisors on each side. Smaller (FA: 42–55 mm; GLS: 17.1–21.9 mm).

T. fulminans. Two lower incisors on each side. Wings brown dorsally, whitish ventrally. Not known north of 5° N.

T. lobata. Two lower incisors on each side. Inner margins of ears meeting close to snout; ears extending well beyond snout when laid forward. White spot between shoulder-blades. Interdental palate markedly constricted at level of posterior premolar. Kenya and Zimbabwe.

T. ventralis. Two lower incisors on each side. Upper lip without well-defined wrinkles. Anterior upper premolar minute; canine and posterior premolar nearly in contact. Not known north of 18° N.

Distribution In Africa, this Palearctic species is found in the Mediterranean Coastal and Afromontane–Afroalpine BZs, in Morocco, Algeria, Tunisia, the Cyrenaica region of Libya, and the Cairo and Giza areas of N Egypt. One doubtful record, based on a mummified specimen with small FA (55 mm), from the Sahara Arid BZ in Algeria (Dorst & Petter 1959), is in very unusual habitat and needs confirmation; it could represent *T. aegyptiaca* (Kowalski & Rzebik-Kowalska 1991). Extraliminally: the Canary Is. and Mediterranean Europe to Central Asia.

Habitat Mainly found in areas with Mediterranean-like vegetation; absent in drier areas. Its presence is locally linked to suitable day-roosts, which include narrow crevices in rocky cliffs or human constructions. In the Aures Mts, Algeria, specimens were mist-netted over a stream (Kowalski & Rzebik-Kowalska 1991). The locality in Cyrenaica is Wadi el Kuff, a limestone mountain area with numerous caves and cracks. The vegetation is shrubland (a type of Maquis) with trees in protected areas; rainfall 300–600 mm per year, mostly in Nov–Feb (Qumsiyeh & Schlitter 1982). In Kyrgyzstan, recorded from sea level to 3100 m (Rybin *et al.* 1989).

Abundance Throughout its distribution, never abundant but, based on hearings of the very low-frequency echolocation calls of this species, which are audible to humans, it is more common than originally estimated from captures.

Adaptations Aspect ratio very high; wing-loading very high. Flight fast and agile with poor manoeuvrability; median speed 50 km/h (Marques *et al.* 2004) (= 13.9 m/sec). Roosts by day in crevices, 2–4 cm wide and variable in depth (15 cm up to several metres), in cliffs or similar human-made structures; sometimes with several entrances (Arlettaz 1990, 1993, Ibáñez & Pérez-Jordá 1998). In Egypt, roosts by day in small caves (Qumsiyeh 1985). The free part of the tail is used as a tactile sensor when moving backwards within crevices (Arlettaz 1993). Although summer-roosts are usually in superficial crevices parallel to the main rocky mass, winter-roosts are deeper and typically located within cracks perpendicular to the cliff face; this allows a deeper positioning in thermally more stable environments. This species is able to live at higher latitudes than any other molossid. In Switzerland, it can stay in torpor as long as eight consecutive days (mean in Jan 3.4 days) (Arlettaz *et al.* 2000). When in torpor, it is able to adjust its body temperature to the environment as long as the ambient roost-temperature does not drop below a threshold situated around 6.5–10°C. Colder roost temperatures induce costly thermogenesis.

Foraging and Food Forages by fast-hawking in open areas, from 10 m to at least 100 m above ground. In Europe, activity starts later than in other species (39–65 min after sunset) and lasts for 10 h without periods of rest (Arlettaz 1990, Marques *et al.* 2004). Foraging areas extend up to 30 km or even farther from the day-roost, although most of the foraging activity takes place between 5 and 15 km from the day-roost (Marques *et al.* 2004). In the European Alps, seems to ascend to passes in the mountains to feed on migratory insects (Arlettaz 1990). In France, Kyrgyzstan and Israel, the diet is mainly moths (65% and 88% by volume), beetles (up to 27%), neuropterans (up to 24%) and hemipterans (up to 12%) according to the locality (Rydell & Arlettaz 1994, Whitaker *et al.* 1994). A diet

comprised largely of tympanate insects (moths and neuropterans) is only possible because the low-frequency echolocation calls emitted by this bat are largely inaudible to these insects and therefore they do not take evasive action to avoid capture (Rydell & Arlettaz 1994).

Echolocation Search-phase call-shape (Switzerland): shallow linear FM. Start-frequency 13 kHz; end-frequency 10.7 kHz; peak-frequency 11.6 kHz; call-duration ca. 15 ms; call repetition rate 1.3–4 per second ($n > 100$ calls; Zbinden & Zingg 1986). These calls, which are audible to humans, are described as a characteristic ‘Tsick’.

Social and Reproductive Behaviour Forages singly or in groups (Arlettaz 1990). In Europe, generally roosts by day in groups of a few dozens, although varying from solitary individuals (normally ♂♂) to maternity colonies of up to 160 bats. Inside the day-roost, usually avoids physical contact with other roost-mates, and rarely forms clusters. Huddling to conserve body-heat occurs only when roost temperature drops below ca. 6.5 °C (Arlettaz *et al.* 2000). In communal roosts, each individual usually defends a small territory against intruders by making loud vocalizations (Arlettaz 1990). These vocalizations are particularly intense when the bats return to the day-roost at sunrise (Arlettaz 1990). Typical social calls are an undulating trill, which alternates up and down in frequency (Ahlén 1990). The mating system, and the mating season, of this species are not well documented. One of six ♂♂ captured in Mar–Apr had scrotal testes in Libya (Qumsiyeh & Schlitter 1982), although ♂♂ display courtship behaviour in mid-Aug and Sep in Kyrgyzstan (Rybin *et al.* 1989) and in the European Alps.

Reproduction and Population Structure Litter-size (Europe): one. In southern Europe and Lebanon, the reproductive chronology is restricted seasonal monoestry, with births in Jun. At ca. 35°N (Aures Mts, Algeria), 3 of 4 ♀♀ were lactating in early Aug (Kowalski & Rzebik-Kowalska 1991). Despite being a Palaearctic species, it is not known whether this species follows a typically temperate zone chronology (with sperm storage or delayed implantation during hibernation). The maximum known longevity record is 13 years (at least) from a ♂ in S Iberia (Ibáñez & Pérez-Jordá 1998).

Predators, Parasites and Diseases Bone remains were found in pellets of Peregrines *Falco peregrinus* and owls *Tyto alba* and *Strix aluco* (Aymerich & García de Castro 1982, Brunet-Lecomte & Delibes 1982, Kock & Nader 1984). Ectoparasites include a flea *Araeopsylla wassifi* (Siphonaptera: Ischnopsyllidae) (Beaucournu & Kowalski 1985); ticks *Carios vespertilionis*, *C. boueti* (Acari: Argasidae); and a mite *Parasteatonyssus hoogstraali* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern (assessed from extralimital as well as African data).

Likely to be threatened by decrease in abundance of its main prey, e.g. moths.

Tadarida thersites RAILER FREE-TAILED BAT (RAILER BAT)

Fr. Tadaride railleuse; Ger. Thersites Bulldoggfledermaus

Tadarida thersites (Thomas, 1903). Ann. Mag. Nat. Hist., ser. 7, 12: 634. Efulen, Cameroon.

Taxonomy Originally *Nyctinomus thersites*. Subgenus *Xiphonycteris*. Synonyms: *occipitalis*. Subspecies: none. Chromosome number (Cameroon): $2n = 48$; $aFN = 62$; one pair large metacentric, three pairs small metacentric, three pairs medium subtelocentric, one pair small subtelocentric and 15 pairs medium-small acrocentric autosomes (Smith *et al.* 1986).

Description Small to very small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; small for an African molossid (FA: 35–42 mm); ears joined by interaural band; M³ with third ridge present

but < half length of second ridge; anterior palatal emargination narrow; wings blackish, ventral pelage dark; ventral flank-stripe black. Not easily distinguished from *T. brachyptera*. Sexes apparently similar. Pelage short (mid-dorsal hairs ca. 2 mm), sleek; dorsally with a conspicuous wide band of naked skin adjacent to the flight-membranes (cf. absent or very narrow in *T. brachyptera*). Dorsal pelage blackish-brown to dark reddish-brown; no grizzling, no spots; hairs with paler, yellowish base. Flanks naked, black. Rump naked, with two tufts of long hairs (as in several other species of *Tadarida* but not often so conspicuous). Ventral pelage medium brown becoming almost black on flanks; mid-ventral markings absent; ventral flank-stripe black and mainly

on the wing. Head not extremely flattened. Upper lip with 5–6 well-defined wrinkles on each side and many spoon-hairs. Ears blackish; relatively small (reaching no more than half-way along muzzle when laid forward); inner margins joined by interaural band with forward-pointing, V-shaped fold in middle. Tragus very small, concealed by antitragus. Antitragus large, trapezoid with rounded corners and broad base. Apparently no interaural crest although hairs are longer and very dense at back of interaural band. Wings blackish, arm bones ventrally pale. Wings inserting higher on body than in *T. brachyptera*. Interfemoral membrane dark brown or blackish.

Skull not extremely dorsoventrally flattened. Anterior of braincase not noticeably elevated above plane of rostrum. Sagittal crest moderate; lambdoid crest very well developed and forming a very prominent, up-turned helmet. Anterior palatal emargination narrow, sometimes U-shaped, sometimes bulb-shaped (narrowest between incisors). Basisphenoid pits moderately deep, small to medium-sized, their width varying from ca. half to equal their distance apart. Upper incisor slightly procumbent; when viewed laterally, not obscured by canine. Upper canines with cingula not enlarged. Anterior upper premolar distinctly taller than cingula of posterior premolar, within toothrow; canine and posterior premolar well separated. M^3 with third ridge present but $<$ half length of second ridge. Two lower incisors on each side, bicuspid, crowded or not crowded. Lower canines with cingula not greatly enlarged, sometimes in contact and sometimes separated. Dental formula: $^{1123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M^3 with third ridge present (but $<$ half length of second ridge) or absent; palatal emargination narrow; FA almost always less than 40 mm (Table 20, p. 488):

Tadarida brachyptera. Ventral pelage (including flanks) pale; no ventral flank-stripe in contrasting colour. Dorsally, the band of naked skin adjacent to flight-membranes is narrow and inconspicuous. Wing inserting lower on body.

T. nanula. Forearm shorter (27–31 mm). Ventral pelage moderately pale. Upper incisor procumbent. M^3 with third ridge absent.

T. petersoni. Forearm usually shorter (33–35 mm). Ventral pelage pale.

T. spurrelli. Forearm much shorter (27–30 mm). Ventral pelage white merging into brown on flanks. In lateral view, upper incisor obscured by upper canine. In adult ♂♂ and some adult ♀♀, cingula of lower canines greatly enlarged and in contact, forming arch over minute incisors. Usually one lower incisor on each side.

T. bakarii. See in profile of *T. brachyptera*.

Distribution Endemic to Africa. Recorded, somewhat disjunctly, from Rainforest BZ and Rainforest–Savanna Mosaic from Sierra Leone to Cameroon (excluding Togo and Benin), and from Cameroon to NE DR Congo, Uganda and Rwanda, and also from Cameroon to SC DR Congo. Not yet recorded from much of the Congolian rainforest in central Africa. There are uncertain records from the Coastal Forest Mosaic BZ on Zanzibar I. (questioned by Koopman

Tadarida thersites

1993) and Mozambique I. (questioned by Smithers & Lobão Tello 1976 and Koopman 1993), which are not mapped. Mapped from country checklists (see order Chiroptera), Smith *et al.* (1986), Van Cakenberghe *et al.* (1999) and other literature (mentioned below) and museum records.

Habitat Recorded from lowland rainforest, secondary forest, areas of invasive Guinea savanna woodland, and mosaics of rainforest and secondary grassland.

Abundance Uncertain. Common on Bioko I. at least in lowland areas and cities (Juste & Ibáñez 1994) and at some localities in mainland Equatorial Guinea (formerly Rio Muni) (Jones 1971). Based on museum collections and literature, probably fairly common elsewhere.

Adaptations Roosts by day in hollow trees, under corrugated iron roofs, in cracks in fabric of buildings, and in road culverts and drains (Lang & Chapin 1917b, Rosevear 1965, Happold 1987). Sometimes roosts with *T. brachyptera* and *T. congica*. Has been recorded flying over water (Jones 1971).

Foraging and Food No information.

Social and Reproductive Behaviour Has been found roosting singly, but more often in small groups of unspecified size and composition (Rosevear 1965). Catch size and sex ratios in catches of *T. thersites* mist-netted over a pool in Uganda varied from month to month; ♀♀ were caught more often than ♂♂ except in Jan and Jul when numbers of ♂♂ and ♀♀ were equal (Kingdon 1974). However, no details of mist-netting times or durations are given and it is not known if the results reflect changes in the local abundance of this species, differences in the behaviour of ♂♂ and ♀♀, or differences in the mist-netting procedures.

Reproduction and Population Structure Litter-size: no published records. At 0–1°N in Uganda, the reproductive chronology appears to be seasonal bimodal polyoestry with births in Mar and Sep (Kingdon 1974). Based on the relative numbers of ♂♂ and ♀♀ mist-netted each month over a pool, and whether or not the ♀♀ were pregnant, Kingdon concluded that mating occurs in Jan and Jul, that gestation is ca. 2.5 months and that the lactation period is ca. 3.5 months, but no details of this study are given, no voucher specimens are mentioned and, although these conclusions are plausible, they need confirmation.

Predators, Parasites and Diseases Ectoparasites include fleas *Lagaropsylla incerta*, *L. obliqua*, *L. convexa* (Siphonaptera: Ischnopsyllidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Tadarida trevori TREVOR'S FREE-TAILED BAT

Fr. Tadaride de Trevor; Ger. Trevors' Bulldoggfledermaus

Tadarida trevori (J. A. Allen, 1917). Bull. Am. Mus. Nat. Hist. 37: 468. Faradje, Orientale, DR Congo.

Taxonomy Originally *Mops trevori*. Subgenus *Mops*. Treated as subspecies of *T. congica* by Koopman (1965), but considered to be a distinct species by Peterson (1972), Freeman (1981) and Koopman (1993, 1994). Synonyms: none. Tentatively not considered to include *T. niangarae* (but see profile of *T. niangarae*). Chromosome number: not known.

Description Small microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; medium-large for an African molossid (FA: 51–55 mm); ears joined by interaural band; M³ with third ridge present but < half length of second ridge; anterior palatal emargination closed; wings dark brown; ventral pelage pale brown, darker on flanks; no ventral flank-stripe in contrasting colour; dorsal pelage not dark brown to almost black; crown not darker than back. Sexes apparently similar in most parameters, but data are available for only three ♂♂. Pelage sleek; nape naked or nearly so; mid-dorsal hairs ca. 6 mm. Dorsal pelage (grey-phase) medium sepia brown or yellowish-brown; no grizzling, no spots; hairs unicoloured or with paler base. There is a poorly defined patch of dark pelage behind and below the ear. Ventral pelage pale greyish-brown, pale pinkish-grey or pale yellowish-brown, becoming darker on flanks; mid-ventral markings absent; no ventral flank-stripe in contrasting colour. Orange-phase, dorsal pelage pale rusty-brown; ventral pelage pinkish-buff. Head not extremely flattened. Upper lip with 8–9 well-defined wrinkles on each side and many spoon-hairs. Ears dark brown, relative length medium (almost reaching snout when laid forward); inner margins joined across forehead by a thin, flexible interaural band with a forward-pointing, V-shaped fold in the middle. Tragus very small,

concealed by antitragus. Antitragus large, trapezoid. Interaural crest probably absent although, in both sexes, the posterior side of the interaural band supports dense, dark brown hairs. Gular gland: no information. Wings semi-translucent, lightly to heavily pigmented with dark brown. Third metacarpal (both sexes): 53–56 mm, n = 16; fourth metacarpal: 51–54 mm, n = 16 (cf. *T. congica*). Interfemoral membrane dark brown.

Skull not extremely dorsoventrally flattened. Anterior of braincase slightly elevated above plane of rostrum. Sagittal crest moderate; lambdoid crest well developed. Anterior palatal emargination closed; incisive foramina visible. Basisphenoid pits deep, large, their width much greater than their distance apart. Anterior upper premolar ca. same height as cingulum of posterior premolar; within tooththrow. M³ with third ridge present but < half length of second. Two lower incisors on each side, bicuspid, crowded. Lower canines fairly long and robust; cingula not greatly enlarged, usually separated. Dental formula: $1^{123}/_{2123} = 30$.

Geographic Variation None recorded.

Similar Species Five other African *Tadarida* have the following combination of characters: ears joined by interaural band; M³ with third ridge present (but usually* < half length of second ridge) or absent; anterior palatal emargination closed; FA: >40 mm (Table 20, p. 488). *In *T. condylura*, the length of the third ridge is variable and can be up to half length of second ridge.

Tadarida demonstrator. Smaller (FA: 41–46 mm). Males with pair of glands between penis and anus. Dorsal pelage hoary. No dark patch behind and below each ear.

T. condylura. Forearm almost always shorter (45–51 mm). Wings semi-translucent pale greyish-brown. Ventral flank-stripe white or whitish, contrasting with darker flanks. Skull with basisphenoid pits shallow and small.

T. niveiventer. Forearm shorter (44–48 mm). Skull with basisphenoid pits moderate in depth and size. Ventral pelage mostly white or cream.

T. congica. FA usually longer (54–58 mm); 3rd and 4th metacarpals usually longer (see Description). Dorsal pelage dark brown to black. Interaural band much thicker. Skull usually larger (GLS: 24.9–27.4 mm). M^3 with third ridge absent.

T. midas. Larger (FA: 59–67 mm; GLS: 25.8–29.5 mm). M^3 with third ridge absent.

Distribution Endemic to Africa. Mostly recorded disjunctly from the Northern and Eastern Rainforest–Savanna Mosaics, from Guinea to W Ghana, from SW Nigeria, possibly from Central African Republic, and from NE DR Congo, S Sudan and Uganda (Peterson 1972, J. Fahr pers. comm.). Also recorded from the Guinea Savanna BZ in Côte d'Ivoire. Records from Mt Bero, Guinea and Côte d'Ivoire are from J. Fahr (pers. comm.). Specimens, previously identified as *T. congica*, from Nigeria (Bergmans 1977b) and Ghana (Jeffrey 1975, Koopman *et al.* 1995, Grubb *et al.* 1998) are considered to represent *T. trevori* by Fahr *et al.* (2006). A record of *T. congica* from Bamingui-Bangoran N. P., Central African Republic (Spinage 1988) is likely to represent *T. trevori* (inferred from its distribution in Guinea woodland savanna by J. Fahr pers. comm.).

Habitat Primarily recorded from forest edges and areas of invasive Guinea woodland savanna in the Rainforest–Savanna Mosaic, but extending into undifferentiated woodland and *Isobertinia* woodland. Recorded from 'rocky hill country covered with savanna bush or open woodland', 'over a shallow stream with riverine forest on one side and open savanna on the other', and over ponds and streams in open areas within forest or at edges of forest, which suggests that *T. trevori* does not usually inhabit closed rainforest (Peterson 1972). Possibly it sometimes commutes from open habitats to forage above the canopy of closed forest, but this needs confirmation.

Abundance Uncertain. Poorly represented in museum collections, which suggests that *T. trevori* is uncommon or rare; however, it is not easy to catch and may be more abundant than records indicate.

Remarks The holotype, from 03° 50' N (Faradje, NE DR Congo), had fed on good-sized Coleoptera and contained one large embryo in late Sep (Lang & Chapin 1917b). Ectoparasites include a flea *Lagaropsylla alloides* (Siphonaptera: Ischnopsyllidae) described by Smit (1977) (host given as *T. congica* but specimen re-identified by J. Fahr pers. comm.).

Conservation IUCN Category: Data Deficient.

Apparently rare. Inhabits rainforest–savanna mosaic in very heavily populated areas where shifting agriculture and extraction of wood are ongoing threats, and apparently does not roost in buildings.

Tadarida ventralis GIANT FREE-TAILED BAT

Fr. Grande tadaride africaine; Ger. Große Bulldoggfledermaus

Tadarida ventralis (Heuglin, 1861). Nova. Acta. Acad. Caes. Leop.-Carol. 29 (8): 4, 11. Keren, Eritrea.

Taxonomy Originally *Nyctinomus* (*Dysopes*) *ventralis*. Subgenus *Tadarida*. Synonyms: *africana*. History of synonymy of *ventralis* and *africana* is summarized by Kock (1975). Chromosome number: not known.

Description Medium-sized microbat without noseleaf and with terminal portion of tail projecting freely from posterior margin of interfemoral membrane; large for an African molossid and the largest African *Tadarida*; ears relatively small, inner margins meet to form V-shaped valley; M^3 with third ridge > half length of second ridge; palatal emargination wide; wings dark brown; no ventral flank-stripe in contrasting colour; two lower incisors on each side. Sexes similar except ♂♂ on average heavier than ♀♀. Pelage velvety, sometimes glossy; mid-dorsal hairs 4–5 mm. Dorsal pelage (grey-phase) chocolate brown, rusty-brown or dark brown without spots or flecking; hairs with beige or cream at base. Ventral pelage paler with white or cream mid-ventral stripe; ventral flank-stripe same colour as flank but with longer hairs. Orange-phase: dorsal pelage orange-brown, ventral pelage yellowish. Head not extremely flattened. Upper lip without well-defined wrinkles; comparatively few spoon-hairs. Ears brown, relatively small (extending to ca. middle of muzzle when laid forward); inner margins meeting on forehead to form a V-shaped valley. Tragus large, roughly rectangular, not concealed by antitragus. Antitragus low, triangular, not much larger than tragus. No interaural crest. Gular gland naked, conspicuous (especially in ♂♂), and often ringed by grey hairs. Wings and interfemoral membrane semi-translucent, dark brown to almost black. Ventral sides of forearms naked and whitish; ventral sides of legs naked and brownish. Foot without raised plantar pad on sole.

Skull not extremely dorsoventrally flattened. Anterior of braincase not noticeably elevated above plane of rostrum. Sagittal crest very weakly developed; lambdoid crest well developed laterally but absent dorsally. Anterior palatal emargination wide. Interdental palate broad, narrowing smoothly (but slightly) to canines. Basisphenoid pits deep, medium-sized, their width slightly greater than their distance apart to almost twice their distance apart. Upper incisors long and close together. Anterior upper premolar variable (it can be lower, level with, or taller than the cingulum of posterior premolar); in tooththrow or slightly displaced labially; canine and posterior premolar nearly in contact, sometimes in contact. M^3 with third ridge > half length of second ridge. Two lower incisors on each side, bicuspid and crowded. Lower canines well developed; cingula enlarged and in contact or almost so, or separated. Dental formula: $^{1123}/_{2123} = 30$.

Geographical Variation No information.

Similar Species Four other *Tadarida* in Africa have ears with inner margins meeting, or almost meeting, to form a V-shaped valley:

Tadarida aegyptiaca. Much smaller (FA: 42–55 mm; GLS: 17.1–21.9 mm).

*Tadarida ventralis*

T. fulminans. Ventral flank-stripe white, cream or yellowish. Foot with plantar pad. Skull usually smaller and less robust (GLS: 21.6–24.4 mm). Upper incisor shorter.

T. lobata. Inner margins of ears meeting close to snout; ears extending well beyond snout when laid forward. White spot between shoulder-blades. Skull with interorbital constriction slight. Anterior upper premolar large; canine and posterior premolar well separated. Lower canines slender; cingula separated by incisors.

T. teniotis. Three lower incisors on each side. Upper lip with five well-defined wrinkles. Anterior upper premolar large; canine and posterior premolar well separated. North Africa.

Distribution Endemic to Africa. Recorded from scattered localities in Afromontane–Afroalpine, Somalia–Masai Bushland and Zambezian Woodland BZs, and Eastern Rainforest–Savanna Mosaic. Recorded from Eritrea and Ethiopia, S Sudan, E DR Congo, Kenya, Tanzania, Malawi, Zimbabwe, Mozambique and from somewhere unspecified in the former Transvaal (South Africa) (Harrison 1971, Hill & Morris 1971, Lagen *et al.* 1974, Koopman 1975, Cotterill 1996b, 2001c). Most records are from Kenya (Cotterill 2001c). Voucher specimens (USNM) for two localities in Mozambique (Chiuta and Vila Gouveia) mapped by Smithers & Lobão Tello (1976) as *T. africana* actually represent *T. fulminans*.

Habitat Mostly recorded from dry woodland savannas (including *Acacia–Commiphora* bushland, drier types of miombo woodland and mopane woodland), but also recorded from montane habitats (including Keren, Eritrea, at 1400 m, Fatam R. [= Blue Nile Gorge]

at Great Abbai, Ethiopia at 1900 m, and the Kenyan Highlands), and from semi-desert grassland and shrubland near L. Turkana, Kenya. The availability of rock crevices in which to roost appears to be a major determinant of their occurrence in these vegetation zones (Cotterill 2001c).

Abundance Not known.

Remarks Only five specimens were known until 1971 (Hayman & Hill 1971) but more have been collected since, especially from Kenya (Cotterill 2001c). Nevertheless, all aspects of the biology of *T. ventralis* remain barely known. A pregnant ♀ with one foetus (CR = 30 mm) was collected from a rock crevice in E Zambia in mid-Nov (Ansell 1986b), and a skull was recovered from an owl pellet underneath crevices in a large granitic overhang in S Zimbabwe. This site was occupied as day-roosts by *T. fulminans* and large numbers of *T. ansorgei* (Cotterill 1996b). Two specimens from Kenya were collected as they emerged from the roofs of houses (Start 1966, Cotterill 1996b). *Tadarida ventralis* occurs sympatrically with *T. lobata* at Maungu Hill, Kenya (Cotterill 2001c).

Conservation IUCN Category: Data Deficient.

Remains poorly known despite intensive sampling effort. Most records are historical. Has a wide geographic range, but is inferred to be threatened by pesticides and loss of habitat.

* Since this profile was submitted, it has been indicated that two of these taxa should be raised to family status: the genus *Cistugo* to Cistugidae (Lack *et al.* 2010), and the subfamily Miniopterinae to Miniopteridae (Miller-Butterworth *et al.* 2007). As major updating was not possible, both are still presented here as vespertilionids.

This is a very large polytypic family that is distributed throughout the world wherever there are enough insects to eat and day-roosts of some sort: only the polar regions, the highest mountains and the most arid deserts are uninhabited by vespertilionids. Having 48 extant genera and 407 extant species (Simmons 2005), this is the largest family of bats and, among mammals, it is second in size only to the rodent family Muridae. The family Vespertilionidae is also one of the most widely dispersed families of mammals. In Africa, there are ca. 93 species (some 'species' almost certainly contain two or more cryptic species, and two species, *Pipistrellus permixtus* and *Phoniscus aerea*, are unlikely to be genuine African species). Simmons (2005) recognizes 19 genera which have African representatives: here, partly because their species contents are uncertain, two genera (*Neoromicia* and *Hypsugo*) are included in *Pipistrellus sensu lato*. Vespertilionids have a simple muzzle without a noseleaf (Figure 32i), and the tail is completely enclosed by the interfemoral membrane (except for part of the terminal vertebra in some species) (Figure 33i). Most are brown, grey or blackish-brown with paler bellies and are often dubbed 'little brown bats'. However, some vespertilionids are unexpectedly colourful, with delicate to spectacular markings, and are among the most beautiful of all mammals. For example, the Pied Butterfly Bat *Glauconycteris superba* has a striking pattern of white patches and lines on a black background, and black wings. Welwitsch's Bat *Myotis welwitschii* is rufous and cream with spectacular wings that are black with bright orange-red markings. The Variegated Butterfly Bat *Glauconycteris variegata* is often creamy-

fawn with yellowish wings patterned with fine brown 'veins' so that they resemble dry leaves, and the Rufous Myotis *Myotis bocagii* has a subspecies that is bright rufous dorsally and cream ventrally with very dark brown ears, snout and wings.

African vespertilionids include *Pipistrellus musculus* (FA: 25, WT: 3–4 g), which is one of the smallest of all mammals, and *Scotophilus nigrita* (FA: 77–88 mm, WT: 88–91 g), which is one of the largest microbats. Most, however, are small to very small; some medium-sized. Most have pelage that is shortish and dense, or woolly, and most have slightly elongated bodies. In other characters, vespertilionids are very varied. The head can be rounded to very flat; the muzzle conical, and short to long. The ears (Figure 116) are comparatively simple, usually widely separated but joined in two genera, often relatively short (means 23–48% of FA), sometimes relatively long (means 72–97% of FA). The tragus is well developed and its shape is often used to identify genera and species (Figure 116). The eyes are small and sometimes hidden by pelage. The wings are very varied in shape and colour; the second finger has a metacarpal and one short phalanx (Figure 117). The hindlimbs vary in relative length and, in some species, are modified for climbing over slippery leaves. The toes (except the first [hallux]) have three phalanges. The interfemoral membrane is broad and long. Usually it fully encloses

Figure 116. Ears and tragi of African bats in the family Vespertilionidae to show differences between subfamilies. (a) Ears joined (e.g. *Barbastella*, Vespertilioninae). (b) Ear not funnel-shaped; widely separated from other ear (e.g. *Miniopterus*, Miniopterinae). (c) Ear funnel-shaped; widely separated from other ear (e.g. *Kerivoula*, Kerivoulinae). (d) Tragus short and blunt as in (d) *Scotoecus*, Vespertilioninae; (e) *Laephotis*, Vespertilioninae; (f) *Glauconycteris*, Vespertilioninae and (g) *Miniopterus*, Miniopterinae. Tragus long and narrow but not sharply pointed as in (h) *Otonycteris*, Vespertilioninae and (i) *Myotis*, Myotinae. Tragus long, narrow and sharply pointed as in (j) and (k) *Kerivoula* spp., Kerivoulinae.

Figure 117. Variations in the length of the second phalanx of the third finger in relation to length of the first phalanx of third finger, in African Vespertilionidae. (a) Second phalanx ca. as long as first (most Vespertilioninae). (b) Second phalanx ca. twice as long as first (*Glauconycteris*, Vespertilioninae). (c) Second phalanx about three times as long as first (*Miniopterus*, Miniopterinae).

the tail, which extends to the membrane's V-shaped posterior border although, in some species, the terminal vertebra protrudes beyond the interfemoral membrane. Relative tail length varies from short to long (27–54% of TL). Females usually have one pair of nipples in the pectoral region; some species (but only *Otonycteris hemprichii* in Africa) have two pairs. There are no pubic nipples. The skull has a rostrum that varies from short to moderately long, and the cranial region varies from flat to highly domed. There are no postorbital processes and no enlarged supraorbital ridges. The sagittal and lambdoid crests are usually low but may combine to form a helmet in the largest members of some genera. The premaxillae have nasal branches that are usually widely separated; the palatal branches are absent and consequently the palate has a deep to very deep, wide anterior emargination. Within this family, there is a trend towards shortening of the jaws and a concomitant loss of incisor and premolar teeth: there may be a total of 38 teeth, or as few as 28. Consequently the dental formula varies from genus to genus and is used diagnostically (Figure 119).

There is greater diversity in the adaptations of the vespertilionids than in any other family of bats in Africa. In African species (excluding *Cistugo* and *Miniopterus*), aspect ratios range from low to medium, and wing-loadings range from very low to extremely high (the majority have low aspect ratios and low or very low wing-loadings). Tip shapes range from short and rounded to long and pointed. In *Miniopterus*, aspect ratios range from medium to very high, and wing-loadings from low to medium. Most vespertilionids, including all African species, are insectivorous (a few species from elsewhere eat fish), but *Nyctalus lasiopterus* also preys on small birds migrating during the night (see profile). The flying abilities, foraging strategies and diets of vespertilionids are as varied as their wing morphology. Foraging behaviour includes fast-hawking (e.g. *Nyctalus*, *Pipistrellus savii*), moderately fast-hawking (e.g. *Miniopterus*, *Pipistrellus tenuipinnis*, *Scotophilus*, *Scotoecus* and at least one *Glauconycteris*), slow-hawking (most other species), gleaning (e.g. *Eptesicus serotinus*, *Kerivoula* spp., some *Myotis* spp., *Otonycteris hemprichii* and *Plecotus christii*) and trawling (e.g. *Myotis bocagii*, *M. capaccinii*). Some species exemplify more than one strategy. There are species of vespertilionids in almost all environments, from open to densely cluttered. Many vespertilionids use their wings to flick a flying insect into a temporary pouch created between the legs by the interfemoral membrane, and then tuck the head down to remove the insect and eat it. Their aerial acrobatics, associated with the pursuit, capture and manipulation of prey, are spectacular to watch and, as their name implies, vesper bats often forage in the evening and can be watched with ease. They often forage in groups. The adaptive radiation within this family has been so extensive that there are many examples of convergent evolution. In Africa, for example, the wing morphology and foraging habits of vespertilionids in the genus *Kerivoula* are similar to those of nycterids while, at the other end of the continuum, vespertilionids such as *Scotophilus* and *Scotoecus* have converged towards the emballonurids and molossids. This convergence also embraces echolocation. The majority of African vespertilionids for which data are available, emit high intensity steep FM/QCF calls (Figure 118), but

Figure 118. Sonograms of individual echolocation calls emitted by 13 species of vespertilionids from Malawi to indicate differences between species and, in some cases, differences associated with echolocating in different situations: all bats flying < 3 m above ground except where indicated (M. Happold unpubl.). (a) *Laephotis botswanae*; (b) *Pipistrellus nanus*; (c) *P. zuluensis*; (d) *P. capensis*; (e) *P. cf. melckorum*; (f), (g) and (h) *P. rueppellii*; (i) *Nycticeinops schlieffeni* (well above ground); (j) *N. schlieffeni* (< 3 m above ground); (k) *Scotophilus dinganii* (search-phase); (l) and (m) *S. dinganii* (approach-phase); (n) *S. viridis*; (o) and (p) *Miniopterus fraterculus*; (q) *Myotis bocagii* (flying near ground); (r) *Myotis tricolor* (flying near ground) and (s) *Myotis welwitschii* (flying near ground). See also Figure 27.

there are 'whispering' bats in the vespertilionid genus *Kerivoula* as there are in the Nycteridae and Megadermatidae, and some of the high-flying vespertilionids such as *Scotophilus* and *Scotoecus*, emit shallow to very shallow FM search-phase calls that are remarkably similar to those emitted by high-flying Molossidae (Figure 27). A less obvious example concerns the use of Doppler shift to distinguish targets that are fluttering from those that are not. Rhinolophids and hipposiderids are well known to do this by perceiving Doppler-shifted changes in echoes of the CF-components of their calls when they are reflected from fluttering targets but, recently, it has been demonstrated that bats emitting FM calls may also be able to do this by detecting Doppler-shifted 'frequency smears' in echoes reflected from fluttering targets (Taylor 1990). Because many vespertilionids forage in groups, their high-intensity echolocation calls, when made audible to our ears by a bat-detector, make an almost deafening racket of harsh staccato noises not unlike machine-gunfire. These bats emit their echolocation calls through the mouth, so individuals with bared teeth and threatening grimaces are usually just having a good 'look' at you with no intention to bite at all! It is unfortunate that so many artists make bats look savage and repulsive when, in fact, they are usually gentle and attractive. Most vespertilionids make vocalizations, in the contexts of communication and the expression of pain and/or fear, which are audible to humans as sounds such as squeaking, twittering, buzzing and nickering.

Vespertilionids are moderately adapted for cursorial locomotion and are able to move over horizontal, sloping and vertical surfaces. However, with the exception of *Miniopterus*, they cannot furl their flight-membranes as effectively as emballonurids and molossids, and they do not normally scuttle or climb except when moving very short distances between a landing place and a roost-site. Some species have pads on the wrists and heels to facilitate climbing slippery banana leaves. Vespertilionids, as a family, exploit the full range of day-roosts known to be used by bats (but with limitations on where they roost within some of these day-roosts), and some utilize day-roosts that are not used or seldom used by bats of other families in Africa.

These include inside the furred leaves of banana plants (exploited by *Pipistrellus nanus* and *Myotis bocagii*), weaver-bird and sunbird nests (*Kerivoula*), holes in trees made by nesting woodpeckers and barbets (*Scotophilus* but also some molossids), and crevices in bark and spaces under loose sheets of bark (*Barbastella*, *Mimetillus*, and some species of *Laephotis*, *Myotis*, *Nyctalus* and *Pipistrellus* [and also some molossids]). With few exceptions, vespertilionids cling in contact with the sloping or horizontal surfaces of their day-roosts: very few ever roost hanging freely. Consequently, vespertilionids rarely compete with bats of other families that hang freely from ceilings. Vespertilionids roost singly or in small to very large groups, and group-members typically roost in close contact with each other. Many African vespertilionids go into torpor during the day, even in the tropics, but true hibernation is rare. Some exceptions include *Barbastella barbastellus*, *Nyctalus leisleri*, *Pipistrellus pipistrellus*, *Myotis* spp. and *Miniopterus schreibersii*, which hibernate in North Africa, and *Myotis tricolor*, *Miniopterus fraterculus* and *M. natalensis*, which hibernate in South Africa. The social behaviour and mating systems of African vespertilionids have received little attention: exceptions are *Myotis bocagii* and *Pipistrellus nanus*. Some appear to have solitary organizations, some establish pairs and harems and many live in small to very large groups of various compositions. Maternity colonies are established by many species. The reproductive strategies of African vespertilionids are not as diverse as might be expected, except in litter size. Most vespertilionids are monotocous but there are many species in Africa (and elsewhere) that have litters of 1–2, usually two, or 2–3 (and one non-African species, *Lasiurus borealis*, regularly has four, and occasionally five, young). All African vespertilionids (and the vast majority elsewhere) for which data are available, are seasonally monoestrous with the exceptions in Africa of *Myotis bocagii*, which is polyoestrous in Gabon, and *Pipistrellus nanus*, which is perhaps aseasonally monoestrous in some equatorial localities (assuming the data are not from several cryptic or misidentified species). Polyoestrous individuals have also been reported for *Mimetillus molonyi* and *Pipistrellus rendalli* (see species profiles), although the reproductive chronologies of

these species are not yet fully understood. The advantages of timing spermatogenesis and lactation to coincide with seasons of maximum abundance of insects and/or optimal temperatures has led to the evolution of delays between copulation and parturition. These delays, which usually occur during the cold dry season or winter, include sperm storage and delayed fertilization (*Myotis tricolor*, *Pipistrellus capensis*, *P. nanus*), delayed implantation (*Scotophilus leucogaster*, *Miniopterus fraterculus*, *M. natalensis*, *M. schreibersii* and probably *M. minor*) and retarded embryonic development (*M. schreibersii*, *Scotophilus viridis* and perhaps *P. rusticus*) (see species profiles). The ♀♀ of some species carry their neonates while foraging but leave them in the roost when they become larger and heavier.

The geological range of the family Vespertilionidae is middle Eocene to Recent in Europe, late Oligocene to Recent in North America, middle Miocene to Recent in Africa and Asia, Pleistocene to Recent in the West Indies, South America and Australasia, and Recent over the remainder of the present geographic range (Koopman 1984).

Of the 91 species definitely known to occur in Africa, 48 species are only or mainly found in the tropics, 26 species occur in both tropical and temperate regions and 17 species (of which 16 are Palearctic species) occur only in temperate regions. Of the 90 species for which data are available, 23 are only or mainly found in savannas, 22 only or mainly in forests, 20 in both forests and savannas, 15 in Mediterranean habitats, six in arid regions, and four in both savanna and arid regions. Thirty-eight species (42%) are found in montane habitats, but only five of these species have been found only in montane habitats. Because vespertilionids are very diverse in their wing morphology and flight, and in their feeding and roosting habits, it is not surprising that there are considerably more than one species at most localities (except localities in some arid regions), for example: four species along the Nile R. at or near Khartoum, six at Kikwit, DR Congo (rainforest), six at Luluabourg, DR Congo (rainforest–savanna mosaic), six on Zomba Plateau, Malawi (montane forest and grassland, 1500–1800 m), 12 in Taï N. P., Côte d'Ivoire (rainforest), 13 in Liwonde N. P., Malawi (miombo woodland) and 17 in Comoe N. P., Côte d'Ivoire (forest–savanna mosaic) (refs. Hayman *et al.* 1966, Koopman 1975, Happold & Happold 1997, Van Cakenberghe *et al.* 1999, Fahr & Kalko 2011).

The family Vespertilionidae was placed by itself in the superfamily Vespertilionoidae by Simmons (1998) although some authors, including Teeling *et al.* (2005), also include the Molossidae in this superfamily. However, recent studies based on molecular data contradict some of the groupings based on morphological data and, pending resolution of the controversies, no chiropteran superfamilies are recognized by Simmons (2005). There is also some uncertainty about the monophyly of the Vespertilionidae: *Miniopterus* (currently in subfamily Miniopterinae) may represent a distinct family. Indeed, since this profile was submitted, Miller-Butterworth *et al.* (2007) have confirmed that *Miniopterus* does represent a distinct family (Miniopteridae) and, furthermore, Lack *et al.* (2010) concluded that *Cistugo* (placed here in the Vespertilionidae, subfamily Myotinae) also represents a distinct family (Cistugidae). The Vespertilionidae are divided into subfamilies but the number, composition and affinities of the subfamilies is perhaps not yet fully understood. However, Simmons (2005) recognizes six subfamilies of which four are represented in Africa, and they are profiled here because it was not possible to incorporate the recent recognition of the families Cistugidae and Miniopteridae (see above).

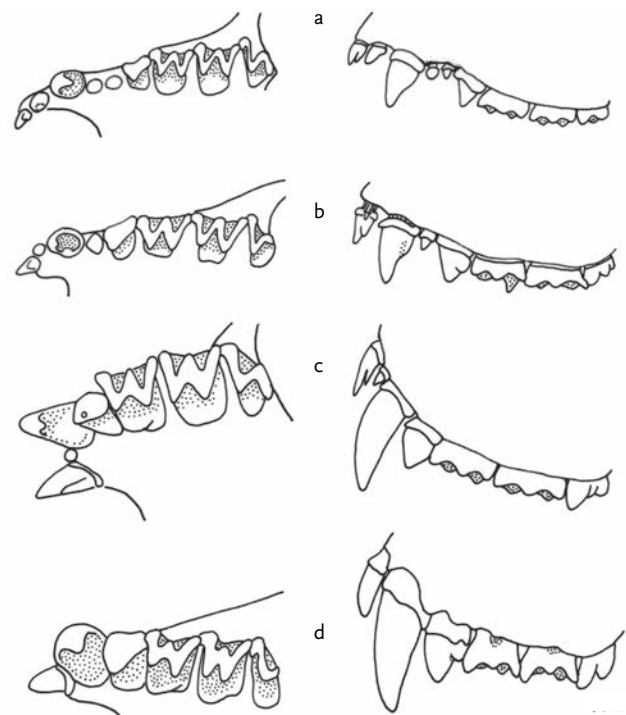

Figure 119. Variations in the number of upper incisors and cheekteeth on each side in African Vespertilionidae. *Left*: occlusal views of teeth on left side of upper jaw. *Right*: lateral views of labial sides of the same teeth. (a) Two incisors and six cheekteeth (e.g. *Myotis*). (b) Two incisors and five cheekteeth (e.g. *Plecotus*). (c) Two incisors and four cheekteeth (e.g. *Glauconycteris*). (d) One incisor and four cheekteeth (e.g. *Scotophilus*).

The characters by which the four subfamilies (*sensu* Simmons 2005) can be distinguished in Africa, and the African genera in each subfamily, are listed below and illustrated in Figures 116, 117 and 119.

Vespertilioninae. Second phalanx of third finger ca. as long as the first phalanx or longer but not more than twice as long as the first; ears not funnel-shaped; tragus short and blunt or long and narrow but not sharply pointed; pelage not frizzled; four or five upper cheekteeth; baculum present. All genera except those listed below.

Myotinae. Second phalanx of third finger ca. as long as the first; ears not funnel-shaped; tragus long and narrow but not sharply pointed; pelage not frizzled; six upper cheekteeth; baculum present. *Cistugo*, *Myotis*.

Miniopterinae. Second phalanx of third finger ca. three times longer than the first; braincase high and rounded; ears not funnel-shaped; tragus short and blunt; pelage not frizzled; five upper cheekteeth; baculum absent. *Miniopterus*.

Kerivoulinae. Second phalanx of third finger ca. as long as the first; braincase high and rounded; ears funnel-shaped with deep emargination below tip; tragus long, narrow and sharply pointed; pelage frizzled; six upper cheekteeth; baculum: no information. *Kerivoula* and (very dubiously) *Phoniscus*.

Following Simmons (2005), the subfamilies are presented in the above order. The African genera in each subfamily are presented in alphabetical order irrespective of any relationships between them.

Meredith Happold

Subfamily VESPERTILIONINAE – Barbastelles, Serotines, Butterfly Bats, Long-eared Bats, Noctules, Pipistrelles, House Bats and others

Vespertilioninae Gray, 1821. London Med. Repos. 15: 229.

Diagnostic combination of characters: second phalanx of third finger ca. as long the first or longer but not more than twice as long as the first (Figure 117); ears not funnel-shaped (Figure 116); tragus short and blunt, or long and narrow, but not sharply pointed (Figure 116); less than six upper cheekteeth (Figure 119). This subfamily includes 37 genera (Simmons 2005) of which 14 occur in Africa (Simmons 2005) but, of the latter, only 12 are presented here (*Hypsugo* and *Neoromicia*

being provisionally treated as *Pipistrellus* [*sensu lato*] for reasons given below – see genus *Pipistrellus*). The phylogenetic relationships of the genera in this subfamily have been investigated many times, numerous hypotheses have been advanced, and various tribes have been described (e.g. Hill & Harrison 1987, Menu 1987, Koopman 1994, Volleth & Heller 1994, Hooper & Van Den Bussche 2001 and many others). Simmons (2005) recognizes seven tribes of which five are represented

Table 21. Key to the African genera in the subfamily Vespertilioninae. Ears are said to be relatively short if 23–48% of FA, medium if 49–72% of FA and long if 73–97% of FA. Measurements and distributions pertain only to Africa.

| Number of lower cheek-teeth | Number of upper incisors | Number of upper cheek-teeth | Ears joined at base | Ear length (mm) (relative length) | FA (mm) | Miscellaneous | Genus |
|-----------------------------|--------------------------|-----------------------------|---------------------|-----------------------------------|---------|--|---------------------------------------|
| 6 | 2 | 5 | Yes | 32–40 (Long) | 36–42 | North Africa, Sudan, Eritrea, Ethiopia | <i>Plecotus</i>
(3 species) |
| 5 | 2 | 5 | Yes | 13–18 (Short) | 36–44 | North Africa | <i>Barbastella</i>
(2 species) |
| 5 | 2 | 5 | No | 13–23 (Short) | 41–64 | Fifth finger shortened (about = 4th metacarpal)
North Africa | <i>Nyctalus</i>
(2 species) |
| 5 | 2 | 4 or 5 | No | 5–16 (Short) | 23–39 | Fifth finger not shortened (> 4th metacarpal)
Head not flattened
No body pattern; wings not reticulated
Outer margin of ear not reaching mouth | <i>Pipistrellus</i>
(28 species) |
| 5 | 2 | 4 | No | 15–25 (Medium) | 30–41 | Head slightly flattened
No body pattern; wings not reticulated
Outer margin of ear not reaching mouth | <i>Laephotis</i>
(4 species) |
| 5 | 2 | 4 | No | 9–14 (Short) | 27–31 | Head conspicuously flattened
No body pattern; wings not reticulated
Outer margin of ear not reaching mouth | <i>Mimetillus</i>
(1 species) |
| 5 | 2 | 4 | No | 6–16 (Short) | 32–48 | Head not flattened
Most with body pattern of spots and/or lines, or reticulated wings
Outer margin of ear reaching mouth
Lower lip with lobe at posterior angle | <i>Glauconycteris</i>
(12 species) |
| 5 | 2 | 4 | No | 10–20 (Short) | 34–54 | Head not flattened
No body pattern; wings not reticulated
Outer margin of ear not reaching mouth
Lower lip without lobe at posterior angle | <i>Eptesicus</i>
(5 species) |
| 5 | 1 | 4 | No | 30–41 (Long) | 50–65 | | <i>Otonycteris</i>
(1 species) |
| 5 | 1 | 4 | No | 11–24 (Short) | 41–88 | Penis relatively short
Tragus relatively moderately long
Posterior upper molar with two ridges | <i>Scotophilus</i>
(6 species) |
| 5 | 1 | 4 | No | 9–13 (Short) | 28–35 | Penis short (5.6–6.2 mm)
Upper canine with anterior surface rounded not grooved
Posterior upper molar with three ridges
Anterior lower premolar ca. half height of posterior premolar | <i>Nycticeinops</i>
(1 species) |
| 5 | 1 | 4 or 5 | No | 9–15 (Short) | 28–40 | Penis extremely long (ca. 9–16 mm)
Upper canine with anterior surface flat and grooved
Posterior upper molar with three ridges
Anterior lower premolar at least two-thirds height of posterior premolar, usually subequal | <i>Scotoecus</i>
(2 species) |

in Africa: the total number of genera in these tribes is given in brackets, and the named genera are those represented in Africa.

Eptesicini (3 genera): *Eptesicus*.

Nycticeiini (8 genera): *Nycticeinops*, *Scotoecus*, *Scotophilus*.

Pipistrellini (4 genera): *Nyctalus*, *Pipistrellus* (*sensu stricto*).

Plectotini (6 genera): *Barbastella*, *Otonycteris*, *Plecotus*.

Vespertilionini (13 genera): *Glauconycteris*, *Hypsugo*, *Laephotis*, *Mimetillus*, *Neoromicia*.

However, because it is unlikely that relationships between genera are fully understood, tribal affinities are not included in most species profiles here.

The status of some genera is also controversial and there have been many changes of opinion since Koopman (1993), including the following examples. (a) Following Hill & Harrison (1987) and others, *Glauconycteris* is recognized as a distinct genus instead of a subgenus of *Chalinolobus*. (b) Following Horáček & Hanák (1986), Hill & Harrison (1987) and others, *Nycticeinops* is recognized as a distinct genus instead of a subgenus of *Nycticeus*. (c) Following Hill & Harrison (1987), Menu (1987), Volleth & Tidemann (1991), Volleth *et al.* (2001) and others, many species traditionally in *Eptesicus* have been removed, with the result that, in Africa, *Eptesicus* is now considered to be represented by only five species (details in Genus *Eptesicus*). The species which have been removed from *Eptesicus* (*brunneus*, *capensis*,

grandidieri [as *flavescens*], *guineensis*, cf. *melckorum*, *rendalli*, *somaticus*, *tenuipinnis* and *zuluensis*), have been placed in *Neoromicia* by several authors, including Simmons (2005), but the placement of some of these species in *Neoromicia* is controversial (e.g. Hooper & Van Den Bussche 2001), and so too is the placement of *nanus* in *Neoromicia* by (Simmons 2005). (d) Following Horáček & Hanák (1986) and others, *savii*, which was previously in *Pipistrellus*, is considered to belong to the genus *Hypsugo*, and this, and the generic status of *Hypsugo*, is well supported by morphological, chromosomal and molecular evidence. However, often in the absence of evidence other than morphology, many other species formerly in *Pipistrellus* have now been placed in *Hypsugo* (see Simmons 2005) and this also is controversial. Therefore, pending resolution of the species contents of *Neoromicia* and *Hypsugo*, and also for convenience, all of the *Pipistrellus*-like species in Africa are presented here as species of *Pipistrellus* (*sensu lato*). With this exception, the African species in the subfamily Vespertilioninae are placed in the genera recognized by Simmons (2005), but some genera (*Plecotus*, *Pipistrellus*) contain new species, and some forms given specific status by Simmons (2005) are considered here to be subspecies.

The 12 genera of Vespertilioninae represented in Africa can be distinguished by the characters given in Table 21. In the text, they are presented in alphabetical order irrespective of any relationships that might exist between them.

Meredith Happold

GENUS *Barbastella*

Barbastelles

Barbastella Gray, 1821. London Med. Repos. 15: 300. Type species: *Vespertilio barbastellus* Schreber, 1774.

Barbastella barbastellus.

A polytypic genus with two species, both found in North Africa. Diagnostic combination of characters: five upper and five lower cheekteeth and two upper incisors on each side; ears joined at base (as in *Plecotus*) but short (cf. *Plecotus*); tympanic bullae small (cf. large in *Plecotus*). Dental formula $2^{123}/_{3123} = 34$ (as in *Nyctalus* and most African *Pipistrellus*). Selected characters of *Barbastella* are illustrated in Figure 120.

Morphologic, bacular and karyotypic data suggest close affinity with *Plecotus*, *Otonycteris* and about three other non-African genera (e.g. Hill & Harrison 1987, Frost & Timm 1992, Tumlison & Douglas 1992, Qumsiyeh & Bickham 1993). Mitochondrial ribosomal sequences

support the relationship with *Plecotus*, but not with *Otonycteris* (Hooper & Van Den Bussche 2001). Simmons (2005) places *Barbastella* in the tribe Plectotini (with both *Otonycteris* and *Plecotus*, and three non-African genera). Some authors consider that *Barbastella* is monotypic (but see profile of *B. leucomelas*). *Barbastella* is distributed from North Africa through Europe, SW Asia, N India to W China and also Japan (Koopman 1994). In Africa, both species have been found in semi-desert habitats but *B. barbastella* is also found in cool montane habitats in NW Africa, whereas *B. leucomelas* has been found only at low altitudes (and probably the only records in Africa are those of vagrants).

The two species are:

B. barbastellus. Pelage, wings and interfemoral membrane pale; ventral pelage pale fawn to off-white; condylobasal length 13–14 mm; tympanic bullae smaller; auditory meati smaller; mastoid region less inflated and without a prominent projecting flange (Figure 121a); outer margin of ear usually with a prominent projecting lobe (Figure 120).

B. leucomelas. Pelage, wings and interfemoral membrane dark, ventral pelage dark grey; condylobasal length 14–15 mm; tympanic bullae larger; auditory meati larger; mastoid region noticeably inflated and with a prominent projecting flange (Figure 121b); outer margin of ear normally without projecting lobe.

Meredith Happold

Figure 120. African *Barbastella*. Flight membranes, and bones of wing, hindlimb and tail of *B. barbastellus*. Left eye, ear and tragus of *B. barbastellus*: note small lobe projecting from middle of outer margin of ear (absent in *B. leucomelas*). Skull of *B. barbastellus* (ZFMK 61.200 from Spain). Occlusal view of upper teeth of *B. barbastellus*.

BELOW: Figure 121. The tympanic regions (left side) of (a) *Barbastella barbastellus* and (b) *B. leucomelas* (after Harrison & Makin 1988).

Barbastella barbastellus WESTERN BARBASTELLE

Fr. Barbastelle d'Europe; Ger. Mopsfledermaus

Barbastella barbastellus (Schreber, 1774). Die Säugethiere 1: 168. Burgundy, France.

Taxonomy Originally *Vespertilio barbastellus*. Synonyms: *barbastelle*, *communis*, *daubentonii*. Subspecies: none. Possibly includes *leucomelas* but, pending further information, *B. leucomelas* is treated as a distinct species here (see profile for *B. leucomelas*). Chromosome number (Turkey): $2n = 32$; $aFN = 50$ (Volleth 1985).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and five lower cheekteeth and two upper incisors on each side; dorsal pelage silvery-black; wings blackish-brown to black; ears joined at base, short for a vespertilionid (13–14 mm), normally with projecting lobe on

outer margin. Pelage silky, dense; mid-dorsal hairs ca. 10 mm. Dorsal pelage dark blackish-brown to black with silvery sheen; hairs dark blackish-brown or black with whitish or yellowish tip. Ventral pelage dark grey; hairs dark blackish-brown with greyish-white to beige tip. Chin, throat and chest darker than belly and flanks. Dorsal pelage of young up to 12 months old is black without silvery sheen. Muzzle short, flat and broad; nostrils opening upwards and outwards between two high, lateral glandular swellings and behind prominent median pad. Ears (Figure 120) blackish, relatively short for a vespertilionid (40.1 [36–46]% of FA, $n = 12$) (cf. relatively long in *Plecotus* and moderately long in *Otonycteris*); forward-facing, inner margins joined at base by low frontal band, outer margin conspicuously notched near base and usually with a small lobe projecting from the middle of the margin (cf. *B. leucomelas*). Ears fold back close to head when bat rests. Tragus reaching just over half height of ear, triangular with long rounded tip, covered with fine hairs. Wings and interfemoral membrane dark brown to black (cf. *B. leucomelas*). Tail 91.6 (70–110)% of HB (Europe).

Skull (Figure 120) with rostrum narrow and weak; braincase elongated and rounded; zygomatic arches slender and without marked dorsal curvature; zygomatic width < mastoid width. Sagittal crest absent or very low; lambdoid crest weakly developed. Tympanic bullae comparatively small (cf. *Plecotus*); smaller than in *B. leucomelas* (Harrison & Makin 1988). Auditory meati comparatively small (cf. *B. leucomelas*); mastoid region less inflated and without a prominent projecting flange (Figure 121a). Inner incisor bicuspid; outer incisor smaller, not reaching level of secondary cusp of inner incisor. Upper canines slender. Two upper premolars on each side; anterior premolar minute (shorter than cingulum of canine), displaced lingually; canine and posterior premolar in contact. Lower incisors (three on each side) tricuspid, arranged in a V-shape with the outer pair the largest. Two lower premolars and three lower molars on each side.

Geographic Variation Uncertain. If new evidence shows *B. leucomelas* is conspecific, it might be considered a subspecies of *B. barbastellus*.

Similar Species The only other African vespertilionids that have ears with inner margins joined are:

Barbastella leucomelas. Outer margin of ear normally without small projecting lobe; ear longer (15–18 mm) and narrower. Pelage, wings and interfemoral membrane pale; ventral pelage pale fawn to off-white. Tympanic bullae and especially the auditory meati larger; mastoid region more inflated and with a prominent projecting flange; lambdoid crest less evident.

Plecotus spp. Ears much longer (32–40 mm). Six lower cheekteeth on each side.

Distribution In Africa, this Palearctic species occurs only in the mountains of the Mediterranean Coastal and Afromontane–Afroalpine BZs in Morocco (Rif, Middle Atlas, High Atlas) (Panouse 1955, Ibáñez 1988, Fonderflick *et al.* 1998). Extralimittally: England and W Europe to Caucasus, also Canary Is. and larger islands in Mediterranean (Simmons 2005).

Habitat In Africa, inhabits cool mountains and semi-desert areas. Associated with forested areas in Europe.

Barbastella barbastellus

Abundance Uncommon throughout much of the African geographic range.

Adaptations Aspect ratio low; wing-loading low (Norberg & Rayner 1987). Based on wing morphology, flight predicted to be slow with great manoeuvrability. In Europe, roosts by day in summer in roof-spaces and cracks in buildings, behind wooden window-shutters, holes in trees and behind bark. Hibernates in winter in caves, mines and fissures. Tolerates low ambient temperatures (ca. –5 to +5 °C) and low as well as high relative humidities (40–96%) (Bogdanowicz & Urbanczyk 1983, Weidner 2000). Migratory movements as far as 290 km were reported by Kepka (1960). For more information, see Rydell & Bogdanowicz (1997).

Echolocation The echolocation calls of *B. barbastellus* are unique among Palearctic bats (Ahlén 1981, 1990). Search-phase calls are of two types – one loud and one weak. (a) Call-shape short CF/FM; calls beginning with a short (1–1.5 ms) CF or narrow bandwidth component, and ending with a short downward FM sweep; start-frequency 35 kHz, end-frequency 28 kHz; call-duration 4 ms; intensity high. (b) Call-shape short CF/FM as above or FM; start-frequency 43 kHz; end-frequency 33 kHz; call-duration 5.2 ms; intensity low. Highest call intensity at 30–35 kHz or 40–43 kHz (Schober & Grimmberger 1987, Ahlén 1990). It is suggested that the bat alternates between the loud and weak calls (Jones 1993). Call repetition-rate: 8–9 calls per second. Calls are emitted through the nose as well as through the mouth.

Foraging and Food No information from Africa. In Europe, forages by slow-hawking above the canopy in forested areas and low over water. Has been reported to glean from foliage but this is doubtful. Small moths make up 70–99% of prey by volume (based on analysis of faeces from Europe and C Asia; Beck 1995, Rydell *et al.* 1996, Sierro & Arlettaz 1997). Has a small gape and weak dentition, therefore its diet does not include large, hard-shelled prey.

Social and Reproductive Behaviour In Europe, hibernates singly, or in clusters in colonies of up to 1000 individuals. In summer, sexes segregate; ♀♀ form maternity colonies of 5–80 individuals; ♂♂ roost in small groups (Schober & Grimmberger 1987, Richarz 1989). Mating takes place in autumn, when the bats return to the hibernacula.

Reproduction and Population Structure Litter-size: normally one, rarely two. Reproductive chronology in Africa not known; in Europe, it is seasonal monoestry with mating in autumn (and sometimes in hibernacula); births from mid-Jun (Schober & Grimmberger 1987). Maximum life-span 23 years. In many hibernacula, there is a predominance of ♂♂ (Schober & Grimmberger 1987).

Predators, Parasites and Diseases Predators in Europe include owls *Asio otus*, *Tyto alba*, *Strix aluco*, *Bubo bubo* and the Beech Marten *Martes foina* (Abeijentsev *et al.* 1956, Urbanczyk 1981). Ectoparasites in Europe include fleas (Siphonaptera) and bat-flies (Diptera), both of which are found occasionally, and mites (Acari), which heavily infest this bat.

Conservation IUCN Category: Near Threatened.

Population fragmented and predicted to decline significantly within next 15 years. Has specific habitat requirements and its habitats are declining.

Measurements

Barbastella barbastellus

FA: 38.1 (36–40) mm, n = 6

WS: n. d.

Barbastella leucomelas EASTERN BARBASTELLE

Fr. Barbastelle asiatique; Ger. Östliche Mopsfledermaus

Barbastella leucomelas (Cretzschmar, 1826). In: Rüppell, Atlas Reise Nordl. Afr., Zool. Säugeth., p. 73. Sinai, Egypt.

Taxonomy Originally *Vespertilio leucomelas*. Synonyms: *blanfordi*, *caspica*, *darjelingensis*, *walteri*. Subspecies: two, of which probably only the nominate occurs in Africa. Considered a subspecies of *Barbastella barbastellus* by Qumsiyeh (1985), but not by Corbet (1978), Harrison & Makin (1988), Harrison & Bates (1991) and Corbet & Hill (1991) and, pending further study, Horáček *et al.* (2000) and Simmons (2005). Chromosome number (Japan): 2n = 32; aFN = 50 (Andō *et al.* 1977).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and five lower cheekteeth and two upper incisors on each side; dorsal pelage silvery-fawn over dark brown; wings pale; ears joined at base, medium-short for a vespertilionid (15–18 mm), without projecting lobe on outer margin. Sexes similar. Pelage silky, dense; mid-dorsal hairs ca. 10 mm. Dorsal pelage dark brown with conspicuous silvery-fawn to golden-beige sheen; hairs dark chocolate brown with fawn to beige at tip. Ventral pelage: pale fawn to off-white (throat occasionally appears darker); hairs dark brown with terminal third pale fawn to off-white. Muzzle short, flat and broad; nostrils opening upwards and outwards between two high, lateral glandular swellings and behind prominent median pad. Ears relatively short (40.2 [36–46]% of FA, n = 4) (cf. relatively long in *Plecotus* and moderately long in *Otonycteris*), forward-facing, joined at base by low frontal band; outer margin conspicuously notched near base and without small projecting lobe (cf. *B. barbastella*). Ears fold back close to head when bat rests. Tragus long with covering of fine hairs; tip rounded.

Wings and interfemoral membrane pale brown, semi-translucent (cf. *B. barbastellus*). Tibia 47.8 (46–51)% of FA, n = 4. Tail 105 (96–119)% of HB, n = 4. Baculum (Turkmenistan) lanceolate in dorsal view; proximal part comparatively wide, stout and with well-marked furrow (cf. *B. barbastella* from Europe) (Strelkov 1987).

Skull with rostrum narrow and weak; braincase elongated and rounded; zygomatic arches slender and without marked dorsal curvature; zygomatic width < mastoid width. Supraorbital ridges poorly developed; sagittal crest very low or absent; lambdoid crest very weakly developed and less evident than in *B. barbastella*. Tympanic bullae comparatively small (cf. *Plecotus*), but larger than in *B. barbastella* (Harrison & Makin 1988). Auditory meati comparatively large (cf. *B. barbastella*); mastoid region inflated and with a prominent projecting flange (Figure 121b). Dentition as in *B. barbastella*.

Geographic Variation None in Africa.

Similar Species The only other vespertilionids in Africa that have ears with inner margins joined are:

Barbastella barbastellus. Outer margin of ear normally with small projecting lobe ca. half-way between base and tip; ear shorter (13–14 mm) and broader. Pelage, wings and interfemoral membrane dark, ventral pelage dark grey. Tympanic bullae and especially the auditory meati smaller; mastoid region less inflated and without projecting flange; lambdoid crest more evident.

*Barbastella leucomelas*

Plecotus spp. Ears much longer (32–40 mm). Six lower cheekteeth on each side.

Distribution In Africa, the nominate subspecies has been recorded from Sinai (Egypt) and from the Somalia–Masai Bushland BZ in Eritrea, but the reports are few and far between and it seems probable that they are records of vagrants. Von Heuglin (1862, 1877) listed this species from Massawa, Eritrea, and there is a specimen from ‘Erythrea’ in the MCZ, and the holotype is from Sinai. *Barbastella leucomelas* was also recorded from Senegal by de Rochebrune (1883), but there have been no further records of any *Barbastellus* from Senegal (Hayman & Hill 1971): furthermore, this record is more likely to refer to *B. barbastella* than *B. leucomelas*. Extraliminally: the nominate subspecies is known from Arabia and Iran, and *B. l. darjelingensis* is known from S Israel and Iran to N India, Nepal, W China and Japan.

Habitat No details available for the African records other than that Massawa is near the coast and in the semi-desert grassland and shrubland vegetation zone (terminology: White 1983).

Abundance Very rarely recorded in Africa. Has not been recorded in Sinai since the species was described (Corbet 1978).

Remarks Nothing is known about the biology of this species in Africa and there is very little information from elsewhere. Flight heavy and fluttering; sometimes close to ground, sometimes high (Roberts 1977). In Pakistan, roosts by day in crevices under bark and in tree hollows during summer (Roberts 1977). Also roosts in caves, tunnels, mine-shafts and old deserted houses (Cretzschmar 1826, Ognev 1928, Lay 1967). Roosts and forages singly (Roberts 1977). Litter-size (Eastern Europe and northern Asia): one or two (Ognev 1928).

Conservation IUCN Category: Least Concern (assessment based mainly on extralimital data).

GENUS *Eptesicus*

Serotines

Eptesicus Rafinesque, 1820. Ann. Nature, p. 2. Type species: *Eptesicus melanops* Rafinesque, 1820 (= *Vespertilio fuscus* Beauvois, 1796).

A polytypic genus, considered by Hill & Harrison (1987) to contain 19 species, and by Simmons (2005) to contain 23 species of which five occur in Africa (see subfamily Vespertilioninae). Diagnostic combination of characters for African members: invariably four upper and five lower cheekteeth and two upper incisors on each side; ears comparatively and relatively short and not joined at base; 5th finger not shortened (considerably longer than metacarpals of 3rd and 4th fingers) (cf. *Nyctalus*); no body pattern; wings dark coloured, not reticulated; outer margin of ear not reaching mouth;

lower lip without lobe near posterior angle (cf. *Glauconycteris*); FA: >37.8 mm (except *E. floweri*); GLS: >15.0 mm. Dental formula: $\frac{2^{113}}{3_{123}} = 32$. Selected characters of African *Eptesicus* are illustrated in Figure 122. Species of *Pipistrellus* (*sensu lato*) sometimes share most of these characters but African *Eptesicus* (except *E. floweri*) are almost always larger (FA: 38–51 mm; GLS: 15.3–21.3 mm) than African *Pipistrellus* (FA: 23–39 mm; GLS: 10.0–15.4 mm). Furthermore, species of *Eptesicus* invariably have only one upper premolar on each side whereas, in contrast, 20 of the 28 African species of *Pipistrellus*

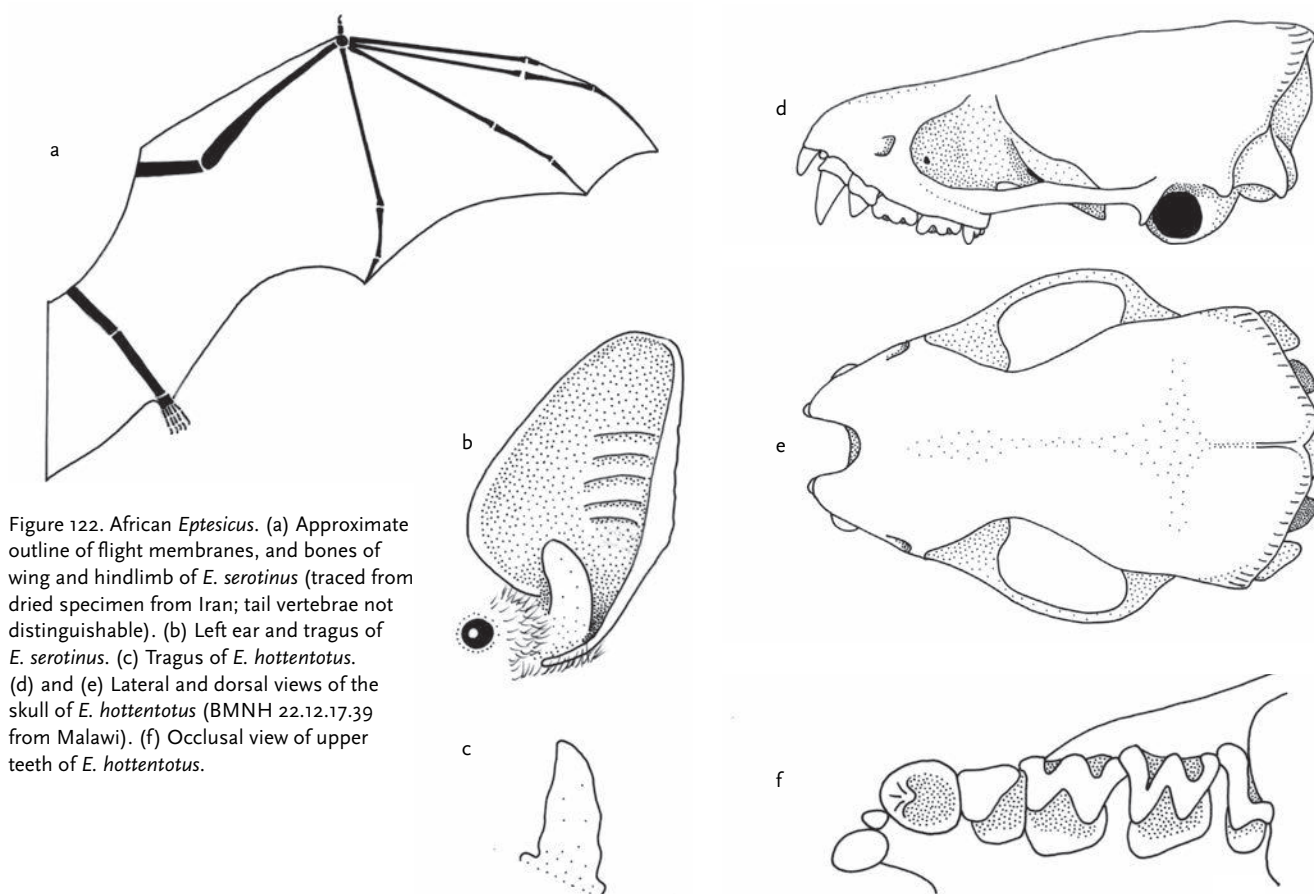

Figure 122. African *Eptesicus*. (a) Approximate outline of flight membranes, and bones of wing and hindlimb of *E. serotinus* (traced from dried specimen from Iran; tail vertebrae not distinguishable). (b) Left ear and tragus of *E. serotinus*. (c) Tragus of *E. hottentotus*. (d) and (e) Lateral and dorsal views of the skull of *E. hottentotus* (BMNH 22.12.17.39 from Malawi). (f) Occlusal view of upper teeth of *E. hottentotus*.

have two upper premolars on each side (although the anterior upper premolar is often minute and therefore sometimes not visible above the gum, and can be absent in some individuals). Also, in *Eptesicus*, the baculum (Figure 123) is more-or-less triangular (cf. variable but not triangular in *Pipistrellus*), and the chromosome number ($2n$) is 50 (cf. variable but always less than 50 in *Pipistrellus*).

Figure 123. Bacula of African *Eptesicus*: dorsal views on left, lateral views of right side on right, tips uppermost. (a) *Eptesicus bottae innesi* from Cairo. (b) *E. hottentotus* from KwaZulu Natal. (c) *E. floweri lowei* from Sudan. (d) *E. serotinus isabellinus* from Morocco. All based on Hill & Harrison (1987). All drawn to same size (for scale drawings, see Hill & Harrison 1987).

Eptesicus was traditionally considered to contain ca. 33 species world-wide (Koopman 1993) and, traditionally, the generic distinction between *Eptesicus* and *Pipistrellus* was based on the absence or presence, respectively, of a second upper premolar (the anterior upper premolar). However, this proved unreliable because tooth reduction appears to have taken place independently in several lineages of the Vespertilionidae. Based on bacular morphology, Hill & Harrison (1987) retained only 19 species in *Eptesicus*, and placed the remaining species into *Neoromicia* (nine species; Africa only) and *Vespadelus* (five species; Australia only), both of which were considered to be subgenera of *Pipistrellus*. This rearrangement is supported by dental morphology (Menu 1987) and chromosomes (Heller & Volleth 1984, Volleth & Tidemann 1991, Volleth *et al.* 2001, Kearney *et al.* 2002). For further details, see genus *Pipistrellus*.

Of the species that remain in *Eptesicus*, five occur in Africa: *E. bottae*, *E. floweri*, *E. hottentotus*, *E. platyops* and *E. serotinus*. The relationships between these taxa are uncertain (Rosevear 1962, Kock 1969a, Ibáñez & Valverde 1985, Schlitter & Aggundey 1986) but, pending revision of the genus, we follow Koopman (1993) and Simmons (2005), and tentatively recognize all of these taxa as distinct species.

Eptesicus – as currently conceived – is distributed almost world-wide (with the exception of the islands of South-East Asia and Australia), in a wide variety of tropical, sub-tropical and temperate forests, woodlands, savannas and deserts. In Africa, one species is found mainly in the Rainforest BZ (Western Nigerian sub-region and Bioko I.), two mainly in savannas, one in the Sahara Arid BZ and one mainly in the Mediterranean Coastal BZ. No members of this genus are known from the Congolian rainforest.

Table 22. Key to the African species in the genus *Eptesicus*. Relative heights of the braincase are based on height as a percentage of GLS (details in Genus *Pipistrellus* and in *Eptesicus* species profiles). Measurements and distributions pertain only to Africa.

| Inner upper incisor | Ventral hairs | FA (mm) | GSL (mm) | Miscellaneous | Species |
|---------------------|---------------|--------------|------------|---|-----------------------|
| Unicuspid | Bicoloured | 48.2 (45–54) | 16.9–21.5 | Braincase relatively low
Savannas of southern and eastern Africa | <i>E. hottentotus</i> |
| Bicuspid | Bicoloured | 45, 50 | 18.8 | Braincase relatively high
Nigeria, Bioko I. and ? Senegal | <i>E. platyops</i> |
| Bicuspid | Bicoloured | 42.2 (38–47) | 15.3–18.0 | Braincase relatively high
Egypt (Cairo district) | <i>E. bottae</i> |
| Bicuspid | Unicoloured | 48.7 (45–52) | 18.1–20.1 | Braincase of medium relative height
Morocco, Algeria and Tunisia (except deep Sahara), to NW Libya | <i>E. serotinus</i> |
| Bicuspid | Unicoloured | 36.5 (34–38) | 12.0, 13.5 | Unique horny warts on forearms, legs and tail
Braincase relatively high
Sudan south of Sahara | <i>E. floweri</i> |

The species occurring in Africa can be distinguished by the characters and distributions given in Table 22. Further information is given in the Similar Species sections in which comparisons are made only between species of *Eptesicus* and *Pipistrellus* that occur in Africa.

For other characters and explanations of terminology, see genus *Pipistrellus*.

Victor Van Cakenberghe & Meredith Happold

Eptesicus bottae **BOTTA’S SEROTINE**

Fr. Sérotine de Botta; Ger. Bottas Breitflügelfledermaus

Eptesicus bottae (Peters, 1869). Monatsber. K. Preuss. Akad. Wiss. Berlin 1869: 406. Yemen. Nader & Kock (1990) limit the type locality to the area between Hodeida, Hays, Ta’izz and Al Muhka in SW Yemen.

Taxonomy Originally *Vesperus bottae*. Sometimes considered to belong to *E. serotinus* or *E. hottentotus*, but Harrison (1964) corrected this misconception. Synonyms: *innesi* and others extralimitally (Koopman 1993). Subspecies: six of which only one, *E. b. innesi*, occurs in Africa (Koopman 1994). Chromosome number (Soviet Central Asia, Greece): 2n = 50; aFN = 48 (Zima & Horáček 1981, Volleth *et al.* 2001).

Description Small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short (13–18 mm); medium-sized for an African *Eptesicus* (FA: 38–47 mm); ventral hairs bicoloured; inner upper incisor bicuspid. Sexes similar in colour; ♀♀ on average slightly larger than ♂♂. Pelage soft, dense; mid-dorsal hairs 7–10 mm. Dorsal pelage dark cream; hairs with dark grey at base. Ventral pelage much paler; hairs whitish with pale greyish-brown bases. Ears brown to blackish-brown, relatively short, subtriangular with tip rounded. Tragus length ca. half of E; breadth almost constant over the entire length, tip blunt. Eyes very small. Wings and interfemoral membrane dark brown to blackish, semi-translucent; wings without white hind-border but sometimes with very narrow pale border. Tail protruding ca. 3.5 mm beyond membrane. Postcalcareal lobe well developed. Baculum short, flat, stout, triangular with rounded corners (Figure 123a; Hill & Harrison 1987) and see also Spitzenberger (1994).

Skull medium-sized for an African *Eptesicus*. Braincase relatively high (43% of GLS, n = 1) and broad (47% of GLS, n = 1). Rostrum fairly broad, flattened dorsally. Profile of forehead region (viewed laterally) weakly concave (for definition, see genus *Pipistrellus*). Occipital helmet present, sagittal and lambdoid crests moderately developed for this genus. Inner upper incisor large, bicuspid. Outer upper incisor very small (only just reaching above cingulum of inner incisor). Anterior upper premolar absent; canine and posterior premolar in contact. Lower molars myotodont (Menu 1987).

Geographic Variation None in Africa.

Similar Species Six other vespertilionids in North Africa have (on each side) two upper incisors, five lower cheekteeth and only one upper premolar or (at least sometimes) only one that is clearly visible above the gum:

Eptesicus serotinus. Ventral hairs unicoloured. Usually larger (FA: 48.7 [45–52] mm; GLS: 18.1–20.1 mm). Morocco to NW Libya.
Pipistrellus (5 spp.). Smaller (FA: 24–38 mm; GLS: 10.8–14.6 mm). Anterior upper premolar usually present although not always visible above gum.

For other African *Eptesicus*, see Table 22, p. 552.

Eptesicus bottae

Distribution In Africa, known only from the Sahara Arid BZ in the Cairo area of Egypt. Extralimittally: the subspecies in Egypt (*E. b. innesi*) occurs in Israel and Jordan (Harrison & Bates 1991); the other subspecies are recorded from Rhodes (Greece), Turkey, SW and SE Arabia, and from Iraq, Iran and Pakistan north-eastwards to NW China and Mongolia (Gaisler 1970, Harrison & Bates 1991, Simmons 2005). Le Berre (1990) mentions the presence of *E. bottae* in Morocco based on a record of *E. isabellinus* from Heim de Balsac (1948), but this record probably represents *E. serotinus isabellinus*, which occurs in NW Africa.

Habitat In SW Asia, apparently restricted to the deserts and semi-desert regions, but probably only occurs in localized areas, such as farmlands near water, where insects and suitable day-roosts are available. In Israel, has been observed 'flying over cultivated fields lined by eucalyptus and tamarisk trees, surrounded by desert' (Harrison & Bates 1991). Feldman *et al.* (2000) mention edges of vegetation and cliffs as the preferred habitat in Israel. In Iraq, found in gardens and date-groves near rivers, but not encountered in desert localities (Harrison & Bates 1991). In Oman, recorded flying over rocky mountain slopes at 1880–2100 m (Harrison & Bates 1991).

Abundance Apparently not very common anywhere. Based on museum records and the literature, the African subspecies is probably rare or very rare.

Adaptations No information for Africa. In Arabia, *E. bottae* is reported to fly strongly and to be noisy in flight (Harrison & Bates 1991). In Israel, flight-speed of 5.70 m/sec was recorded by Holderied *et al.* (2005). In Iraq, has been found roosting by day in buildings, including in crevices beneath the corrugated iron roofing of verandahs (Holderied *et al.* 2005).

Foraging and Food No information for Africa. Elsewhere, *E. bottae* forages by slow-hawking, rather high above ground (Harrison & Bates 1991). Begins foraging at dusk in some localities, but at some time after dusk at others. In Kurdistan, has been seen feeding on numerous insects gathered around an electric light (Harrison & Bates 1991). In Jordan, recorded flying over a pool, but it is not clear if the bats were foraging or coming to drink. In Israel, feeds mainly on Hymenoptera and Lepidoptera (Feldman *et al.* 2000).

Echolocation Search-phase call-shape (Israel) QCF. Start-frequency ca. 41 kHz; end-frequency and peak-frequency (mean \pm S.D.) 32.5 ± 0.87 kHz; call-duration 6.9 ± 1.32 ms; intercall-interval 155.6 ± 61 ms (134–143 calls, Holderied *et al.* 2005). The loudest calls emitted had an intensity of 121 ± 7.8 dB at 10 cm, and it was calculated from this that *E. bottae* would be able to detect large prey and conspecifics up to a distance of 21 m.

Social and Reproductive Behaviour No information.

Reproduction and Population Structure No information for Africa. From Israel, there are records of two ♀♀, each with twin embryos (crown–rump length ca. 14 mm), in Apr (Harrison & Bates 1991).

Predators, Parasites and Diseases Nader & Kock (1989) were unable to find ectoparasites and, although they do not exclude the possible loss of parasites during transport, they suggest that the lack of parasites might be the result of specific nesting sites or habits. This invites investigation.

Conservation IUCN Category: Least Concern (Africa and also extralimittally).

Eptesicus floweri HORN-SKINNED SEROTINE

Fr. Sérotine de Flower; Ger. Warzen-Breitflügelfledermaus

Eptesicus floweri (de Winton, 1901). Ann. Mag. Nat. Hist., ser. 7, 7: 46. Wad Marium, Khartoum, Sudan.

Taxonomy Originally *Glauconycteris floweri*. This species has unique horny warts on the forearms and consequently has been placed in a separate subgenus, *Rhinopterus*, by some authors, including Hayman & Hill (1971), Hill & Harrison (1987) and Koopman (1993, 1994). Synonyms: *lowei*. Subspecies: none recognized but see Geographic Variation. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short (ca. 10 mm); the smallest African *Eptesicus* (FA: 34–38 mm); ventral hairs unicoloured; inner upper incisor bicuspid; unique horny warts on forearms, legs and tail. A poorly known species. Dorsal pelage yellowish-fawn to pale rusty-brown; hairs unicoloured. Ventral pelage yellowish-brown on throat, becoming paler or pure white on abdomen; hairs unicoloured. Muzzle and cheeks, naked, dark brown. Ears dark brown, relatively short, subtriangular with tip rounded. Tragus length ca. 40% of E; anterior margin straight; posterior margin convex with lobe at base; broadest at mid-height. Wings and interfemoral membrane pale brown, wings of holotype of *floweri* (and one other specimen) with very faint pale hind-border, a third specimen with a conspicuous white hind-border (no other information); horny warts (denticles) on arm-wings and anterior three-quarters of interfemoral membrane give the membranes a spotted appearance. The horny warts on the dorsal surfaces of the forearms, tibiae and tail are characteristic of the monotypic subgenus *Rhinopterus*. Postcalcareal lobe fairly well developed. Tail ca. 76% of HB. Baculum short, flat, roughly triangular (Figure 123c, Hill & Harrison 1987).

Skull small for an African *Eptesicus*. Braincase relatively high (42, 43% of GLS, $n = 2$) and broad (47, 50% of GLS, $n = 2$). Rostrum short and broad; dorsal surface almost completely flat with angular margins (therefore clearly distinguishable from the lateral surfaces). Profile of forehead region (viewed laterally) almost straight. No occipital helmet; sagittal crest moderate, low or absent; lambdoid crests moderate to weakly developed. Inner upper incisor bicuspid. Outer upper incisor very small, barely exceeding cingulum of inner incisor. Anterior upper premolar absent; canine and posterior premolar in contact. Lower molars myotodont (G. Bennell pers. comm.).

Geographic Variation No subspecies recognized by Koopman (1994) and Simmons (2005). Braestrup (1935) regarded *E. floweri* as a variable species, there being a smaller form with ventral pelage buff (*floweri*) and a larger form with ventral pelage whitish (formerly *lowei*). Both forms occur sympatrically in some parts of Sudan, so the variation is apparently not geographic. See also Distribution.

Similar Species No other African vespertilionid has horny warts. The South African *notius* was described as a bat with warts and referred to *Rhinopterus*, but it is probable that the warts of this individual were caused by nematodes and this form is now considered a subspecies of *Pipistrellus capensis* (Koopman 1975).

*Eptesicus floweri*

Distribution Endemic to Africa. Known with certainty only from the Sahel Savanna and Sudan Savanna BZs in Sudan (Kock 1969a, Koopman 1975). A specimen from Timbuktu, Mali, is either a small representative of *E. floweri* or a separate form (Braestrup 1935). In this Malinese specimen, the inner upper incisor is unicuspid and the outer upper incisor is two-thirds of the height of the inner (cf. the Sudanese *E. floweri* described above), suggesting this specimen represents a separate form (E. Thorn pers. comm.). Recently, two specimens (EBD 26179-80) were reported from Mahmûdê L., Wilaya Hodh Ech, Mauritania (16° 29.969'N, 07° 42.911'W) by Padial & Ibáñez (2005); not mapped. The FA lengths of these specimens are 33.5 mm (♀) and 33.2 mm (♂); therefore they are slightly smaller than specimens from Sudan and Mali (see Measurements).

Habitat Recorded from *Acacia* wooded grassland and deciduous bushland, semi-desert grassland and shrubland, and mosaics of edaphic grassland with *Acacia* wooded grassland (terminology: White 1983). Two were shot beside a pool in Sudan (NMW). Possibly limited to habitats with *Acacia* spp. (Koopman 1975). The recent specimens from Mauritania were also found in 'Acacia formations of the Sahel' (Padial & Ibáñez 2005).

Abundance Uncertain. De Winton (1901) reported it common at Shendi in N Sudan. Rarely collected.

Remarks Flies slowly and apparently forages near the ground amongst the dense and thorny *Acacia* bushes. Has also been observed flying low over ponds (von Wettstein 1917). Roosts by day in *Acacia*

thickets – low down near the roots of these trees (de Winton 1901). At dusk, individuals crawl up the branches and take flight, uttering a very characteristic squeak, which they continue to make during flight. The horny warts on the wings are also characteristic of the African molossid *Platymops setiger*, and the non-African *Eptesicus nasutus*, suggesting an ecological parallel with these species (E. Thorn pers. comm.).

Conservation IUCN Category: Least Concern.

Acacia senegalensis, the widely distributed tree that provides the roosting sites of this species in Sudan, is a valuable source of Gum Arabic, but the extent to which harvesting of Gum Arabic has affected the abundance of *E. floweri* is not known (D. Kock pers. comm.).

Eptesicus hottentotus LONG-TAILED SEROTINE

Fr. Sérotine hottentote; Ger. Hottentotten-Breitflügelfledermaus

Eptesicus hottentotus (A. Smith, 1833). S. Afr. Quart. J. 2: 59. Uitenhage, Cape Province, South Africa.

Taxonomy Originally *Vespertilio hottentota*. Synonyms: *augusticeps*, *bensoni*, *megalurus*, *pallidior*, *portavernus*, *smithi*. Subspecies: three or four (see Geographic Variation). Chromosome number (Zimbabwe, South Africa): 2n = 50; aFN = 48; X is a medium-sized submetacentric and Y a small acrocentric (Peterson & Nagorsen 1975, Rautenbach *et al.* 1993, Kearney *et al.* 2002).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short for a vespertilionid (14–20 mm); one of the three large African *Eptesicus* (FA: 45–54 mm); ventral hairs bicoloured; inner upper incisor unicuspid (cf. bicuspid in other African *Eptesicus*). Males on average with slightly shorter FA than ♀♀, at least in some parts of geographic range (Namibia). Pelage sleek, soft and dense; mid-dorsal hairs 7–9 mm. Dorsal pelage varying geographically from pale brown to almost black, often with silky sheen; hairs dark at base with paler tips. Ventral pelage paler, often with creamy sheen; hairs with basal two-thirds blackish-brown, terminal third pale greyish-brown with cream or whitish tips. Ears dark brown to blackish, relatively short, tip rounded. Tragus length ca. one-third of E; broadest at base; posterior margin mostly straight but smoothly convex near tip; tip rounded (Figure 122c). Wings and interfemoral membrane brown (when pelage is comparatively pale) to blackish-brown; no white hind-border. Tail 73 (58–84)% of HB, therefore (on average) not relatively longer than in other African *Eptesicus*. Tail with terminal vertebra slightly protruding beyond interfemoral membrane. Postcalcaneal lobe well developed. Baculum short, roughly triangular but with concave sides, flat but with proximal end thicker than distal end (Figure 123b) (Hill & Harrison 1987).

Skull (Figure 122d and e) large for an African *Eptesicus*. Braincase relatively low (38.8 [37–42]% of GLS, n = 19) and narrow (45.7

[42–49]% of GLS, n = 43). Rostrum broad. Profile of forehead region (viewed laterally) straight. Occipital helmet present; sagittal crest slight; lambdoid crest well developed. Inner upper incisor large, unicuspid. Outer upper incisor minute. Anterior upper premolar absent; canine and posterior premolar in contact (Figure 122f). Lower molars myotodont.

Geographic Variation Based on measurements and/or pelage colouration, the following taxa have been given subspecific status by some authors, but more information and material are needed to confirm their status:

E. h. portavernus: SW Kenya. According to Schlitter & Aggundey (1986), this subspecies is larger and heavier than the other subspecies, and has a shorter palate and deeper braincase. Dorsal pelage pale brown; ventral pelage pale tan. However, only two specimens are known.

E. h. bensoni: E Zambia, Malawi and NW Mozambique and across Zimbabwe to E South Africa (Rautenbach *et al.* 1984, Schlitter & Aggundey 1986, Koopman 1994). Dorsal pelage dark brown to almost black; ventral pelage buff.

E. h. pallidior: Namibia to NW Cape Province (Meester *et al.* 1986). Dorsal pelage pale brown to fawn; ventral pelage whitish-buff with irregular darker patches. Considered a synonym of *hottentotus* by Schlitter & Aggundey (1986).

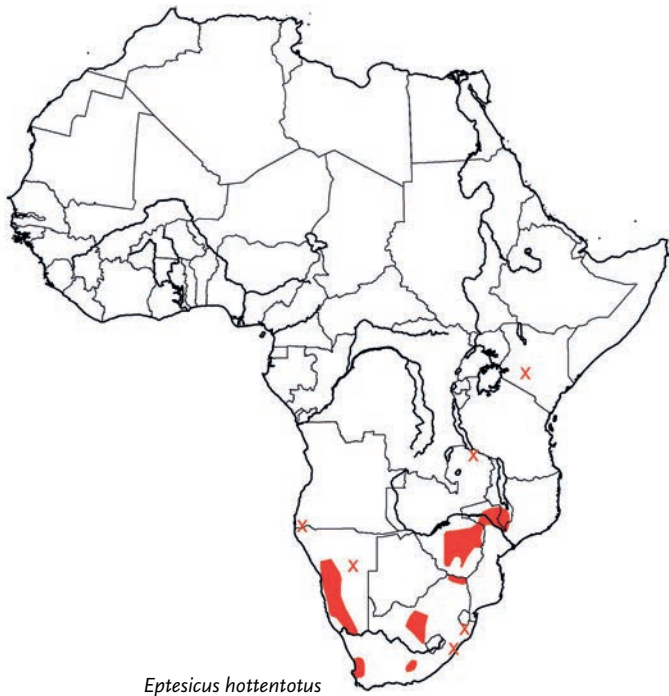

E. h. hottentotus: S and SW Cape Province (Meester *et al.* 1986), not extending far inland. Dorsal pelage deep reddish-brown (Smith 1833) or brown, sometimes with yellowish tinge (specimens from Algeria State Forest; T. Kearney pers. comm.).

Similar Species

Eptesicus serotinus. Inner upper incisor bicuspid. North Africa.

E. bottae. Inner upper incisor bicuspid. Egypt.

E. platyops. Inner upper incisor bicuspid. Senegal, Nigeria and Bioko I.

E. floweri. Much smaller (FA: 34–38 mm; GLS: 12.0, 13.5 mm).

Horny warts on forearms, legs and tail. Sudan.

Pipistrellus (28 African spp.). All much smaller (FA: <40 mm).

Distribution Endemic to Africa. Recorded from the Somalia–Masai Bushland in Naivasha District, Kenya, and from all of the biotic zones in south-central and southern Africa. Recorded from scattered localities in NE Zambia, SW Angola, Zimbabwe, Malawi, NW Mozambique, Namibia and South Africa (Smithers & Lobão Tello 1976, Smithers 1983, Schlitter & Aggundey 1986, Ansell & Dowsett 1988, Crawford-Cabral 1986, Lynch 1994, Watson 1998, Taylor 2000, T. Kearney pers. comm.). Map based on above sources and data from V. Van Cakenberghe (pers. comm.).

Habitat Woodland savannas, and along rivers with permanent water in deserts (e.g. along the Kuiseb R. in the Namib Desert). In Kenya, two were mist-netted in rocky gorges near water. In Malawi, recorded from the rocky escarpment of the Central Plateau (Ntcheu) and from flat country with riverine forest, marshlands and farmlands at the confluence of Shire and Ruwara Rivers (Chiromo). In Zimbabwe, most records are in miombo woodland in the vicinity of gorges and granitic hills (Cotterill 1996a, unpubl.). In South Africa, all records are from the vicinity of cliffs (T. Kearney pers. comm.).

Abundance Locally abundant in NE Zimbabwe (Mutoko District) with repeated records from Bvumba (eastern highlands) and Marondera over the past three decades (Cotterill 1996a). Locally abundant at Cederberg, Western Cape Province, South Africa (T. Kearney pers. comm.). Rarely recorded in Malawi (Happold & Happold 1997).

Adaptations Aspect ratio medium; wing-loading high (Aldridge & Rautenbach 1987). Flight predicted to be slow and manoeuvrable

in clutter, faster while foraging in semi-open areas (Norberg & Rayner 1987). Day-roosts include dry caves, one very wet cave, abandoned mines, a small hollow in rocks at the entrance of an old mine inhabited by *Miniopterus natalensis*, and the outside wall of a building (Smithers 1983, Herselman & Norton 1985). Individuals hang from the walls in very loose formations. Has been mist-netted over water.

Foraging and Food No information. Based on wing morphology, predicted to forage by slow-hawking in both moderately cluttered areas and open spaces. One was mist-netted flying low over a marsh (Herselman & Norton 1985). Six were captured in mist-nets set partly over water and partly over land at the edge of the water; all were caught over the land (Seamark 2005). Diet not known.

Echolocation Calls of one individual (flying in a room) were broad bandwidth calls (20–54 kHz) of short duration (2–4 ms), with peak-frequency 28–32 kHz and usually a strong harmonic component (Taylor 2000). See also Monadjem *et al.* (2010).

Social and Reproductive Behaviour Roosts singly or in small groups. Smithers (1983) did not find more than 3–4 roosting together and noted that they hung together in loose clusters; five were taken from a small hollow in rocks (not known if any escaped) (Herselman & Norton 1985).

Reproduction Litter-size: no information. Reproductive chronology not known. At ca. 17°S (near Mutoko District, NE Zimbabwe), 9 of 9 ♀♀ were either heavily pregnant or lactating at beginning of hot wet season (mid-Nov) (F. P. D. Cotterill unpubl.).

Predators, Parasites and Diseases Ectoparasites include a mite *Pteracarus pusillus* (Acari: Myobiidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Considered threatened in Malawi (Happold & Happold 1997).

Eptesicus platyops LAGOS SEROTINE

Fr. Sérotine à grands yeux; Ger. Lagos-Breitflügelfledermaus

Eptesicus platyops (Thomas, 1901). Ann. Mag. Nat. Hist., ser. 7, 8: 31. Lagos, Western Region, Nigeria.

Taxonomy Originally *Vespertilio platyops*. The taxonomic position of *Eptesicus platyops* is uncertain. Sometimes considered to be a subspecies of *Eptesicus hottentotus* (e.g. Rosevear 1962) or *Eptesicus serotinus* (Ibáñez & Valverde 1985). Kock (1969a) indicates that affinity with *Eptesicus bottae* is another possibility. Koopman (1975) suggests that *platyops*, *loveni* (Granvik, 1924) from Kenya and *hottentotus* might be subspecies of *E. serotinus*, but concludes that all should be retained as separate species until the genus has been thoroughly revised. Schlitter & Aggundey (1986) concluded that the holotype from Lagos was smaller in size than *E. hottentotus portavernus*, and therefore not identical with either *E. hottentotus* or *E. serotinus*. They also showed that the holotype of *loveni* is actually a young *Myotis tricolor*. Synonyms: none. Chromosome number: not known.

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short (ca. 16 mm); one of the three large African *Eptesicus* (FA: 45, 50 mm); ventral hairs bicoloured; inner upper incisor bicuspid. Pelage silky. Dorsal pelage pale to medium fawn; hairs with basal half brown. Ventral pelage paler (cream to whitish); hairs with fawn at base. Ears brown, relatively short; inner margin convex with maximum curvature around basal third; outer margin mainly convex with 1–2 concave sections and a low rounded lobe at the base; tip very rounded. Tragus broad and blunt; broadest part mid-way along length; anterior margin straight; posterior margin convex (without abrupt angle) and with small triangular lobe at base. Wings brown with narrow white hind-border. Interfemoral membrane brown; tail with terminal vertebra protruding beyond membrane; postcalcareal lobe small. Tail ca. 65% of HB. Bacular morphology not known.

Skull large and robust for an African *Eptesicus*. Braincase relatively high (44% of GLS, $n = 1$) and broad (47% of GLS, $n = 1$) although Thomas (1901) described this species as having a very flat skull. Profile of forehead region (viewed laterally) concave (holotype) or straight (IRSN 12426 from Senegal). No occipital helmet; sagittal crest very weak posteriorly, lambdoid crest even weaker. Inner upper incisor large, broad, flattened, bicuspid. Outer upper incisor very small, barely exceeding cingulum of inner incisor. Anterior upper premolar absent. Lower molars myotodont (G. Bennell pers. comm.).

Geographic Variation None.

Similar Species

Eptesicus hottentotus. Inner upper incisor unicuspid. Braincase relatively low. East Africa, south-central Africa and southern Africa.

E. floweri. Much smaller (FA: 34–38 mm). Horny warts on forearms, legs and tail.

E. serotinus. North Africa (see Table 22, p. 552).

E. bottae. North Africa (see Table 22).

Pipistrellus (28 African spp.). Smaller (FA: <40 mm).

*Eptesicus platyops*

Distribution Endemic to Africa. The only records are those of the holotype from Lagos (Nigeria) and three subadult specimens from Bioko I. (all in the Rainforest BZ), and another specimen (IRSN 12426) reputedly from Senegal (biotic zone not known).

Habitat Uncertain. No details are available for the type locality. On Bioko I., the bats were recorded in a cocoa plantation (Ibáñez & Valverde 1985). The specimen reputedly from Senegal presumably came from dry open-woodland country but localities were seldom recorded accurately when these records were made (Rosevear 1965).

Abundance Uncertain. Very rarely collected; probably rare to extremely rare, but the record of three subadult specimens from Bioko I. suggests that it might be more abundant at this locality than elsewhere.

Remarks Nothing else is known about this species.

Conservation IUCN Category: Data Deficient.

Eptesicus serotinus **COMMON SEROTINE**

Fr. Séroline commune; Ger. Breitflügel-Fledermaus

Eptesicus serotinus (Schreber, 1774). Die Säugethiere, 1: 167. France.

Taxonomy Originally *Vespertilio serotinus*. Synonyms: *isabellinus* in Africa, 22 others extraliminally (Simmons 2005). Subspecies: nine; one in Africa. Chromosome number (Tunisia): $2n = 50$; $aFN = 48$ (Baker *et al.* 1974). Since this profile was written, the specific status of *isabellinus* has been restored by Benda *et al.* (2004d), Mayer *et al.* (2007), Artyushin *et al.* (2009) and Juste *et al.* (2009): see Appendix. Consequently, this profile contains some data for *E. serotinus* that does not apply to *E. isabellinus*.

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short for a vespertilionid (12–18 mm); one of the three large African *Eptesicus* (FA: 45–52 mm); ventral hairs unicoloured; inner upper incisor bicuspid. Females slightly larger than ♂. Pelage soft, sleek with silky sheen; mid-dorsal hairs ca. 7–9 mm. Dorsal pelage pale yellowish-brown with creamy sheen; hairs with slightly darker bases. Ventral pelage paler, no distinct boundary with dorsal pelage; hairs unicoloured. Muzzle and cheeks naked, dark brown. Ears dark brown, subtriangular; outer margin with five transverse folds. Tragus length ca. one-third of E; posterior margin smoothly convex; tip bluntly pointed. Wings and interfemoral membrane dark brown; wings without white hind-border. Calcars robust, reaching one-third to half-way to tip of tail. Tail protruding 2–3 mm beyond margin of interfemoral membrane (ca. 1.5 vertebrae). Baculum Y-shaped, flattish but proximal end thicker than distal end (Figure 123d) (Hill & Harrison 1987).

Skull large and robust for an African *Eptesicus*. Braincase of medium relative height (ca. 42% of GLS, $n = 2$) and broad (48–49% of GLS, $n = 3$). Rostrum broad and flat; lachrymal ridges prominent. Profile of forehead region (viewed laterally) straight. No occipital helmet; sagittal crest low but distinct in adults; lambdoid crest moderately developed. Inner upper incisor bicuspid (secondary cusp clearly present in unworn teeth). Outer upper incisor small, slightly higher than cingulum of inner incisor. Anterior upper premolar absent; canine and posterior premolar in contact. Lower molars myotodont.

Geographic Variation None recorded in Africa. Only one of nine subspecies recognized by Simmons (2005) occurs in Africa:

E. s. isabellinus: North Africa (extraliminally Iberian Peninsula). Paler than nominate subspecies (Europe to Caucasus), but similar in cranial dimensions and external characters (Harrison 1963a).

Eptesicus serotinus isabellinus

Similar Species Five other vespertilionids in North Africa have (on each side) two upper incisors, five lower cheekteeth, and only one upper premolar or (at least sometimes) only one which is clearly visible above the gum:

Eptesicus bottae. Ventral hairs bicoloured. Usually smaller (FA: 42.2 [38–47] mm; GLS: 15.3–18.0 mm). Egypt.

Pipistrellus spp. Smaller (FA: 24–38 mm; GLS: 10.8–14.6 mm). Anterior upper premolar usually present although not always visible above gum.

For distinguishing characters and distributions of other African *Eptesicus*, see Table 22, p. 552.

Distribution In Africa, *E. s. isabellinus* is recorded from the Mediterranean Coastal and Afromontane–Afroalpine BZs, and marginally from the adjacent Sahara Arid BZ, in North Africa. Widely distributed in Morocco, Algeria, Tunisia and NW Libya, except in the deep Saharan regions of these countries (Hanák & Elgadi 1984). Extraliminally: *E. s. isabellinus* occurs in Iberian Peninsula. *Eptesicus*

serotinus (excluding *isabellinus*) is widespread from England, Europe and eastwards to Himalayas, Thailand, China and Korea. Also, most islands in the Mediterranean and Lanzarote (Canary Is.). See Taxonomy for new information.

Habitat *Eptesicus s. isabellinus* inhabits lowlands as well as mountains. Has been mist-netted among trees in the coastal zone of Algeria, and over a stream and among rocks in almost treeless regions of the Aures Mts and Saharan Atlas (Kowalski & Rzebik-Kowalska 1991). Well adapted to living in areas occupied by people.

Abundance Common. Although not a cave-dwelling species, records in Africa are numerous and it is the most common species in mist-net sampling from the coastal Oranais to Aures Mts in Algeria.

Adaptations Aspect ratio low; wing-loading medium; wing-tip short and rounded (*E. serotinus*: Norberg & Rayner 1987). Flight fairly slow; mean flight speed in open 9.8 m/s (Norberg 1987). In summer, commonly roosts in buildings, occasionally in hollow trees (especially palm trees in the south). In winter, roosts in buildings and occasionally in underground sites and in cracks in rocks. Sometimes uses night-roosts. Generally stays within 5 km of roosts, but movements of up to 300 km have been recorded between summer- and winter-roosts in Europe. In England, individual home ranges varied from 0.16 to 47.58 km² (Robinson & Stebbings 1997). In North Africa, active on warm nights during winter (Gaisler & Kowalski 1986).

Foraging and Food Mostly forages by slow-hawking, occasionally by gleaning (lands on foliage with wings outstretched). Forages in parklands, along hedges and edges of woodlands (and sometimes within woodlands), over pastures and streams, and around street lights. Flies slowly in large loops above groves and open terrain; often in groups of 2–3 individuals. Foraging is bimodal with main peak at beginning of night and a second lower peak before dawn (Gaisler & Kowalski 1986). In western Europe, *E. serotinus* feeds on large Coleoptera (mainly Scarabaeoideae) and Lepidoptera, also Tipulidae and other small Diptera, Hemiptera and Hymenoptera (Robinson & Stebbings 1993, Beck 1995, Catto *et al.* 1996, Vaughan 1997).

Echolocation No data for Africa. In Europe, search-phase call-shape (5–10 m from obstacles): steep FM/QCF. Intensity high; start-frequency 53 kHz; end-frequency (CF-component) and peak-frequency 24–27 kHz; call-duration 15–20 ms; inter-call interval 150–250 ms (Jones 1993, Tupinier 1996). For variation with height of flight, see Jensen & Miller (1999).

Social and Reproductive Behaviour In Europe, adult ♀♀ establish maternity colonies of ca. 20–60 individuals, which show

high fidelity to their day-roost; at this time, ♂♂ roost singly or in small groups. Mating occurs in early autumn. In winter, both sexes are mainly found singly in cracks and crevices (Arthur & Lemaire 1999).

Reproduction and Population Structure Litter-size (Algeria): 1 (n = 1) or 2 (n = 5) (Kowalski & Rzebik-Kowalska 1991). Reproductive chronology in Africa not known. At 35°41'N (near Oran, Algeria), the majority of ♀♀ mist-netted in late May and mid-Jun were pregnant (most embryos 10–15 mm long); 4 of 4 were lactating in mid-Jul; no data for other months (Kowalski & Rzebik-Kowalska 1991). In Tunisia, 4 of 4 ♀♀ were lactating in early Jun; no data for other months (Baker *et al.* 1974). Weaning age: 6–7 weeks. Maximum life-span: 19.5 years.

Predators, Parasites and Diseases Occasionally preyed on by Barn Owls *Tyto alba*, Pharaoh Eagle-owls *Bubo ascalaphus* and Tawny Owls *Strix aluco* (Aulagnier 1989). Ectoparasites include a flea *Ischnopsylla intermedia* (Siphonaptera: Ischnopsyllidae) and a tick *Argas transgaripepinus* (Acari: Argasidae) (Anciaux de Faveaux 1984). In western Europe, this bat is a principal reservoir for rabies, EBL1; this Lyssavirus is suspected to originate from North Africa (Amengual *et al.* 1997).

Conservation IUCN Category: Least Concern.

In North Africa and Europe, populations are likely to remain stable provided that pesticides do not reduce the numbers of dung beetles and other large insects on which these bats feed.

GENUS *Glauconycteris*

Butterfly Bats

Glauconycteris Dobson, 1875. Proc. Zool. Soc. Lond. 1875: 383. Type species: *Kerivoula poensis* Gray, 1842.

Glauconycteris argentata.

A polytypic genus with 12 species recognized by Simmons (2005). Another species is referred to as *G. cf. poensis* by Fahr & Kalko (2011). Endemic to Africa south of the Sahara. Diagnostic combination of characters: four upper and five lower cheekteeth and two upper incisors on each side; ears short and not joined at base; outer margin of ear reaches mouth, head not flattened; lower lip with lobe at corner of mouth; fifth finger not shortened (considerably longer than metacarpal of fourth finger); six species with body pattern of lines and/or spots, two other species with reticulated wings (dark lines on pale background) and two species without body patterns or reticulated wings. Second phalanx of third finger ca. twice as long as first phalanx (cf. about three times as long as the first in *Miniopterus*, and about equal to the first in most other vespertilionids). Dental formula: $2^{113}/_{3123} = 32$. The flight-membranes, bones of wing, hindlimb and tail of a representative of the genus are shown in Figure 117b, and the ear and tragus, and craniodental characters in Figure 124.

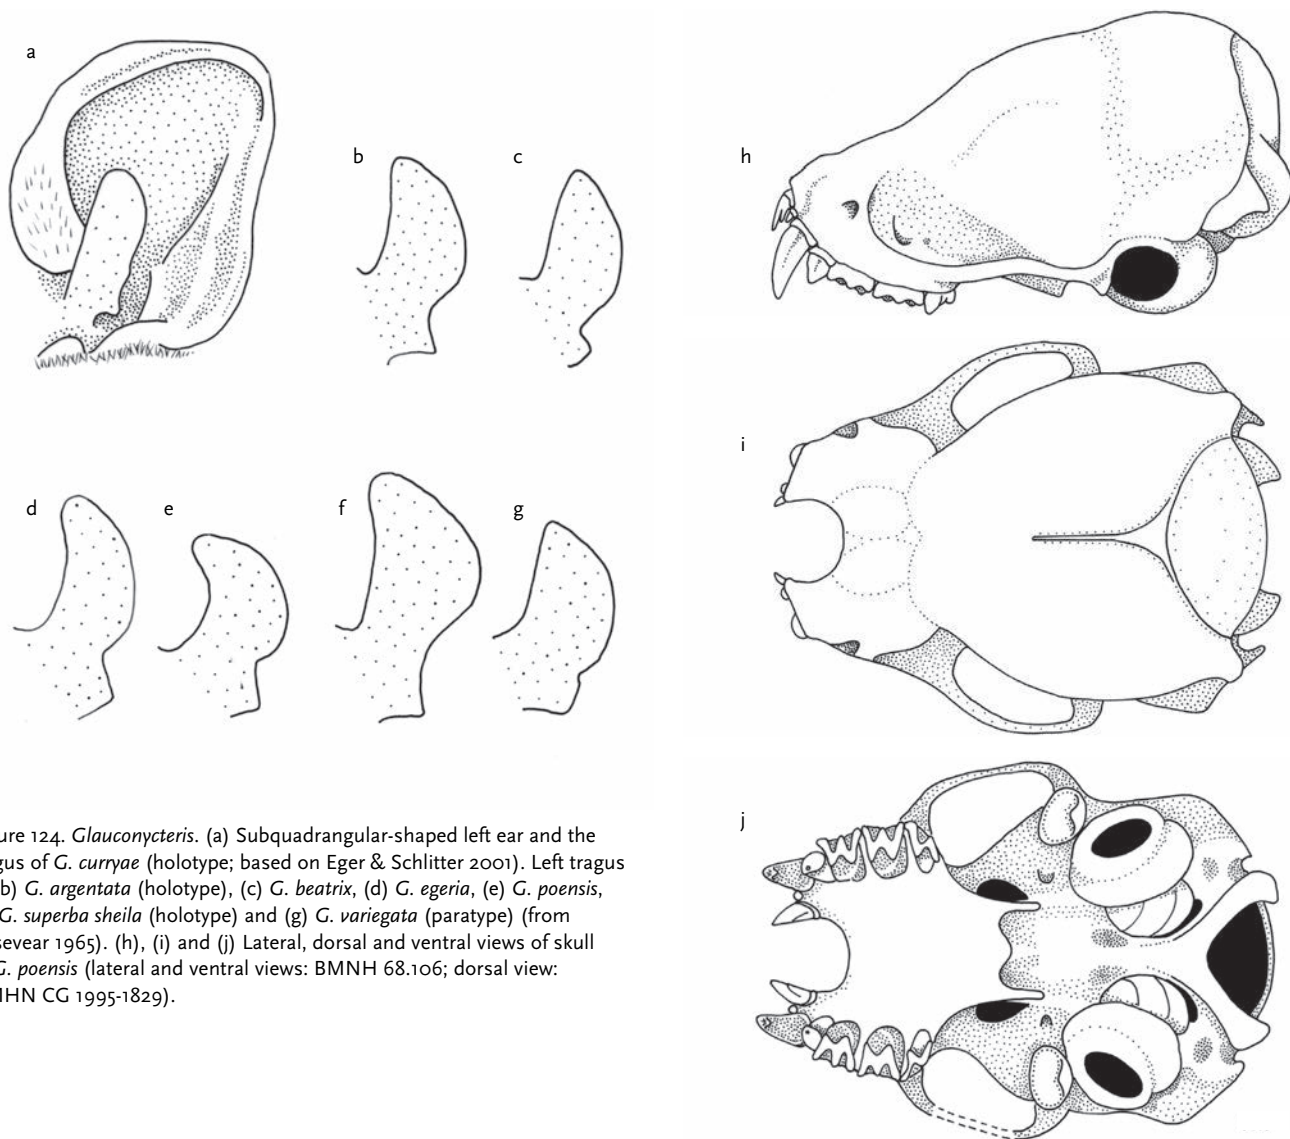

Figure 124. *Glauconycteris*. (a) Subquadrangular-shaped left ear and the tragus of *G. curryae* (holotype; based on Eger & Schlitter 2001). Left tragus of (b) *G. argentata* (holotype), (c) *G. beatrix*, (d) *G. egeria*, (e) *G. poensis*, (f) *G. superba sheila* (holotype) and (g) *G. variegata* (paratype) (from Rosevear 1965). (h), (i) and (j) Lateral, dorsal and ventral views of skull of *G. poensis* (lateral and ventral views: BMNH 68.106; dorsal view: NMNH CG 1995-1829).

Glauconycteris was created as a subgenus of *Chalinolobus*, then raised to generic status by de Winton (1901). Subsequently still sometimes considered a subgenus of *Chalinolobus* (e.g. Smithers 1983, Koopman 1993, 1994) but considered to have generic status by Ellerman *et al.* (1953), Hayman & Hill (1971), Peterson & Smith (1973) and Peterson (1982). *Glauconycteris* is endemic to Africa, whereas *Chalinolobus* occurs in Australia, New Guinea, New Zealand, Norfolk I. and New Caledonia. In *Glauconycteris*, the upper premolar is absent (cf. usually present although very small in *Chalinolobus*). In *Glauconycteris*, but not in *Chalinolobus*, there has been shortening and broadening of the rostrum, elevation of the braincase and (in some species) the evolution of reticulated wings and conspicuous colour patterns. These differences, together with the long isolation of the two taxa, led Hayman & Hill (1971) to retain the generic status of *Glauconycteris*. Bacular morphology (Hill & Harrison 1987) strongly supports the generic status of *Glauconycteris*. In *Glauconycteris*, the baculum is small and somewhat variable, but mostly more or less triangular, with some modification (usually reduction) to a

deeply lobed base with a short distal portion. In some species, the base is slightly or considerably expanded and the distal portion lengthened to a shaft. In contrast, in *Chalinolobus*, the baculum is long, with clearly defined basal lobes, a long cylindrical shaft and an expanded tip. The molecular evidence of Hooper & Van Den Bussche (2003) not only supports the generic status of *Glauconycteris*, but indicates the separation of *Glauconycteris* into the tribe Nycticeiini, and *Chalinolobus* into the tribe Vespertilionini. Simmons (2005), however, places both genera in tribe Vespertilionini. In view of the geographic distributions of *Glauconycteris* and *Chalinolobus*, it is likely that many of the similarities have arisen from convergent evolution (F. P. D. Cotterill pers. comm.).

The taxonomy of some of the African forms is controversial (see *G. beatrix*).

Eight species of *Glauconycteris* are found only in forest habitats (seven mainly or only in rainforest, one in coastal forest mosaic), one in both rainforest and woodland savanna, and two only in woodland savanna.

The species of *Glauconycteris* are distinguished by the characters in Table 23, p. 562, which are:

Wing colour and reticulation. Can be pale or dark. In some species, the venation stands out in a contrasting darker colour creating a net-like pattern, in which case the wings are described as reticulated (Figure 125).

Colour and pattern of dorsal pelage. Of particular importance is the presence or absence of a shoulder-spot (= patch of white or pale dorsal pelage where upper arm joins body) and/or a dorsal flank-stripe (= line of white or pale pelage along the flank above the wing) (Figure 126). The dorsal flank-stripe is sometimes conjoined with the shoulder-spot.

Length and characters of the ears. Characters include outline (rounded or subquadrangular); the shape of the fleshy lobe on the lower lip with which the outer margin of the ear connects; and the shape of a lobule at the base of the inner margin of the ear.

Length of tibia. Mean length ranges from 14.7 to 20.0 mm for this genus, therefore 14.7–16.5 = comparatively short, 16.6–18.2 = medium, 18.3–20.0 = comparatively long.

Forehead region of skull. The dorsal profile (viewed laterally) of the region around the junction of the rostrum and frontal bones can be strongly, moderately or weakly concave (Figure 127).

Inner upper incisor. Can be unicuspid, weakly bicuspid or strongly bicuspid.

Bacular morphology can also be used to distinguish some of the species of *Glauconycteris* (Figure 128).

Meredith Happold

(h) *G. variegata* (form *papilio*) (BMNH 55.409, Mozambique). Figs (c) and (f) from Heller *et al.* (1994); all others from Hill & Harrison (1987). All are dorsal views with tip uppermost. Scale = 1 mm.

Glauconycteris alboguttata **STRIPED BUTTERFLY BAT**

Fr. Glauconyctère à gorge blanche; Ger. Gestreifte Schmetterlingsfledermaus

Glauconycteris alboguttata J. A. Allen, 1917. Bull. Am. Mus. Nat. Hist., 37: 449. Medje, Orientale, DR Congo.

Taxonomy Originally *Glauconycteris alboguttatus* but in this name the gender is incorrect. Synonyms: none. Chromosome number: not known.

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five

lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (13 mm) and rounded; wings uniformly dark brown (not conspicuously reticulated); dorsal pelage sepia brown with shoulder-spot and dorsal flank-stripe on each side; inner upper incisor weakly bicuspid with cusps unequal in size. Sexes similar. Pelage soft; mid-dorsal hairs 7–8 mm. Dorsal pelage sepia brown, sometimes paler

on face; hairs pale sepia brown with blackish-brown at base and sepia brown at tip. White shoulder-spot and narrow white dorsal flank-stripe: joined in some individuals, pale and faint in other individuals. Ventral pelage slightly paler than dorsal pelage. Head high-domed; muzzle short, broad, flattish. Ears pale brown with paler rim, rounded; inner margin semi-circular with backwardly projecting, long, subtriangular lobe; outer margin with semi-circular antitragus and connecting with fleshy lobe on lower lip near corner of mouth. Eyes very small. Wings and interfemoral membrane uniformly dark brown. Tibia of medium length for this genus. Tail shorter than HB ($n = 1$).

Skull moderately large for a *Glauconycteris*. Profile of forehead region (viewed laterally) concave (no details available). Inner upper incisors weakly bicuspid with secondary cusp small although clearly visible. Lower incisors tricuspid, not crowded.

Geographic Variation None recorded.

Similar Species Two other *Glauconycteris* have dark wings and a dorsal flank-stripe:

Glauconycteris egeria. Dorsal pelage dark brown or almost black with conspicuous whitish dorsal flank-stripe but no shoulder-spot. Ears subquadangular, dark brown with conspicuous pale rim. Inner upper incisor strongly bicuspid with cusps ca. equal in size.

G. poensis (sometimes). Dorsal pelage greyish-brown or brownish-grey; hairs bicoloured. Shoulder-spot and/or dorsal flank-stripe either conspicuous, faint or absent.

Distribution Endemic to Africa. Known only from the Rainforest BZ, from four localities in Cameroon (Eger & Schlitter 2001) and four localities in DR Congo (Allen 1917a, Hayman *et al.* 1966, Eger & Schlitter 2001).

Habitat Rainforest.

Abundance Uncertain. Very rarely collected.

Remarks Apparently nothing else is known about the biology of this species.

Conservation IUCN Category: Least Concern.

Population trend not known. Distribution likely to be wider than is currently known.

Glauconycteris argentata COMMON BUTTERFLY BAT

Fr. Glauconyctère argentée; Ger. Silberne Schmetterlingsfledermaus

Glauconycteris argentata (Dobson, 1875). Proc. Zool. Soc. Lond., 1875: 385. Mont Cameroun, Cameroon.

Taxonomy Originally *Chalinolobus argentatus*. Synonyms: none. Chromosome number: not known.

Description Small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (9–14 mm); wings pale

(sometimes faintly, but never conspicuously, reticulated); dorsal pelage golden-fawn to pale greyish-brown with pale (sometimes indistinct) dorsal flank-stripe; inner upper incisor unicuspid or weakly bicuspid. Sexes apparently similar in colour and size. Pelage dense; mid-dorsal hairs ca. 7 mm. Dorsal pelage (in savanna habitats) pale golden-fawn, pale cinnamon or pale greyish-brown; paler on head; hairs tricoloured – beige with brown at base and golden-fawn to greyish-brown at tip. In

Rainforest BZ, dorsal pelage darker and greyer, sometimes with silvery sheen (Rosevear 1965). There is a paler dorsal flank-stripe, which is indistinct in some individuals. Ventral pelage darker and greyer than dorsal pelage. Head high-domed; muzzle short, broad, flattish. Ears rounded, brown; inner margin with moderately long, rounded, backward-pointing lobe at base; outer margin with rectangular antitragus and connecting with a smooth, broad, rounded, fleshy lobe on lower lip near corner of mouth. Tragus as in Figure 124b. Eyes very small. Wings and interfemoral membranes translucent, pale brown; faintly reticulated near body; dorsal pelage extending over anterior quarter of interfemoral membrane. Tibia long for this genus, 17–20 mm. Tail a little shorter than HB.

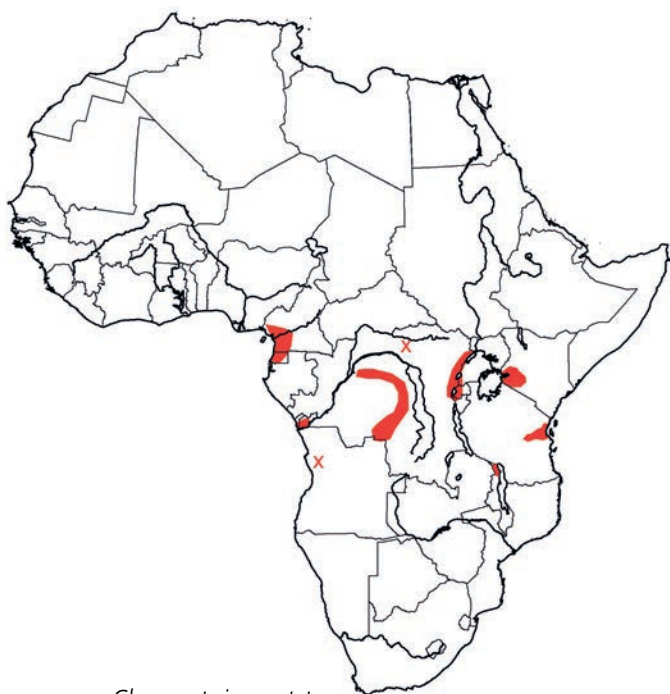

Skull small and profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris* (Figure 127c). Inner upper incisor very long, slender, unicuspid, weakly bicuspid or strongly bicuspid. Lower incisors tricuspid or sometimes with four cusps; not crowded.

Geographic Variation Individuals from rainforest habitats are darker and more grey than those from woodlands (Rosevear 1965), but no subspecies have been described.

Similar Species Only one other *Glauconycteris* has pale wings without any conspicuous reticulation:

Glauconycteris kenyacola. Dorsal pelage dark brown; no shoulder-spot or dorsal flank-stripe. Whitish markings on nose and base of each ear.

Distribution Endemic to Africa. Mostly recorded from the Rainforest BZ and Eastern and Southern Rainforest–Savanna Mosaics, but with some records in the Zambezian Woodland BZ and Coastal Forest Mosaic BZ. Recorded disjunctly (and not in all countries) from Cameroon and Equatorial Guinea (excluding Bioko I.), to Kenya (south of 5°N) and southwards to ca. 10°S in Angola and the Misuku Hills in N Malawi. Mapped from country checklists (see order

Chiroptera), Allen & Loveridge 1933, Cockle *et al.* 1998, BMNH, IRSN.

Habitat Recorded from rainforest habitats at both high and low altitudes (Kingdon 1974), the rainforest–Guinea woodland boundary (Rosevear 1965), bamboo forest (ROM), miombo woodland and the coastal forests of Tanzania (Cockle *et al.* 1998). In East Africa, not found in areas with less than 900 mm annual rainfall (Kingdon 1974). Often recorded over streams, rivers, pools and fish-ponds.

Abundance Uncertain. Fairly common in collections and, based on specimens, this appears to be the most common species in the genus *Glauconycteris* (Rosevear 1965).

Adaptations By day, clings to undersides of fronds of palms including Doum, Coconut and Oil Palms, and *Dracaena* (Rosevear 1965, BMNH). One such day-roost was ca. 7 m above ground.

Foraging and Food No information.

Social and Reproductive Behaviour One palm frond (where these bats roost) may carry more than 30 bats. ‘They cling to the “leaves” near the midrib in groups, only 2–4 on each leaf; they do not hang clear with heads down, but cling to the leaf with their tails towards the midrib, the head of the one nearest the midrib rests upon the back of the next bat in front of him’ (Loveridge 1922 in Rosevear 1965). One roosting group of ca. 25 included four ♂♂ and three ♀♀ of which two were lactating and one was neither pregnant nor lactating. Another group included at least one ♂ and two ♀♀ (BMNH).

Reproduction and Population Structure Loveridge (1937 in Kingdon 1974) recorded that 4 of 8 ♀♀ collected in the Kenya uplands in Mar ‘were carrying young’. At 1–2°S in Kenya, two lactating ♀♀ were recorded on 25 Jun; at the same time, another ♀ was neither pregnant nor lactating (BMNH).

Predators, Parasites and Diseases Ectoparasites include mites *Spinturnix walkeri* (Acari: Spinturnicidae) and *Alabidocarpus glauconycteris* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984). Rift Valley fever virus has been isolated from *G. argentata* (Addy *et al.* 1978).

Conservation IUCN Category: Least Concern.

Glauconycteris beatrix **BEATRIX BUTTERFLY BAT**

Fr. Glauconyctère de Beatrix; Ger. Kleine Schmetterlingsfledermaus

Glauconycteris beatrix Thomas, 1901. Ann. Mag. Nat. Hist., ser. 7, 8: 256. 15 mi (24 km) from mouth of Benito River, Rio Muni, Equatorial Africa.

Taxonomy Synonyms: none. Rosevear (1965) expressed doubt about the distinction of *beatrix* from *poensis*, but the specific status of *beatrix* has been accepted by many, including Peterson & Smith (1973), Hill & Harrison (1987) and Koopman (1989, 1994). Considered to include *humeralis* by some authors but, pending revision, *humeralis* is tentatively treated here as a distinct species. *Glauconycteris humeralis* usually has a white shoulder-spot whereas most specimens of *G. beatrix* have no markings. The holotype, however, has a white shoulder-spot, which led Hayman & Hill (1971) to point out that it remains to be seen whether the shoulder-spot is exceptional in *beatrix*, or whether *beatrix* is an earlier name for *humeralis*, in which case the unspotted 'beatrix' specimens represent either an unnamed form or a variant. Chromosome number (DR Congo): $2n = 22$; $aFN = 40$ (M. Volleth pers. comm.).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (7–12 mm) and rounded; wings dark brown (not conspicuously reticulated); dorsal pelage dark brown, no shoulder-spot (except rarely), no dorsal flank-stripe; tibia long (18–21 mm); inner upper incisor strongly bicuspid. Sexes apparently similar. Pelage dense; mid-dorsal hairs 8–9 mm. Dorsal pelage uniformly dark sepia brown; hairs bicoloured (cf. *G. curryae*) with basal half blackish-brown, terminal half dark sepia brown. White shoulder-spot present in holotype but apparently usually absent (see Taxonomy). Ventral pelage same as dorsal pelage. Head high-domed; muzzle short, broad and flattish. Ears comparatively short for a *Glauconycteris*, very rounded; inner margin with rounded lobe at base; outer margin connecting with well-developed, fleshy lobe on lower lip near corner of mouth. Tragus as in Figure 124c. Wings and interfemoral membrane dark brown, not reticulated. Tibia long for this genus (18–21 mm). Tail either longer, equal to, or shorter than HB. Baculum (dorsal view) triangular with basal portion deeply lobed and distal portion short and blunt (cf. *G. humeralis*) (Figure 128b; Hill & Harrison 1987, Heller *et al.* 1994). Heller *et al.* (1994) suggest that the baculum of SMF 79439 (Figure 128c) is intermediate in shape between that of *G. beatrix* and *G. humeralis* (Figure 128d) (see profile of *G. humeralis*). Skull small; profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris*. Inner upper incisor bicuspid with cusps ca. equal in size or with outer cusp smaller than inner cusp. Lower incisors tricuspid or sometimes 4-cuspid; not crowded.

Geographic Variation None recorded.

Similar Species Three other *Glauconycteris* have dark wings and no dorsal flank-stripe:

Glauconycteris curryae. Dorsal pelage blackish-brown, sepia brown or reddish-brown; head and shoulders slightly paler than rump; hairs conspicuously tricoloured. No dorsal markings. Tibia shorter (14–16 mm). Profile of forehead region of skull strongly concave.

G. humeralis. Dorsal pelage dark brown with shoulder-spot (except rarely).

G. poensis (sometimes). Dorsal pelage medium to dark greyish sepia brown or brownish-grey; hairs tricoloured. Shoulder-spot and/or dorsal flank-stripe either conspicuous, faint or absent. Tibia often shorter (18.0 [16–19] mm). Inner upper incisor weakly bicuspid.

Distribution Endemic to Africa. Recorded from the Rainforest BZ and Southern Rainforest–Savanna Mosaic, from Côte d'Ivoire, Ghana, Nigeria and Cameroon, and southwards to Equatorial Guinea (including Bioko I.), Gabon and N Angola. Probably also extends across the Rainforest BZ to Irangi, E DR Congo (Heller *et al.* 1994), where it is sympatric with *G. humeralis*. Mapped from country checklists (see

Glauconycteris beatrix

order Chiroptera) with some exclusions, Sanderson 1939, Adam & Aellen 1975, Eger & Schlitter 2001, BMNH, SMF.

Habitat Predominantly lowland rainforest, but also forest habitats just outside the rainforest zone. In Nigeria, one was found by a waterhole in secondary forest (Happold 1987). On Bioko I., recorded from forests and cocoa plantations (Juste & Ibáñez 1994). One was found in swamp forest in Taï N. P., Côte d'Ivoire (Fahr & Kalko 2011).

Abundance Uncertain. Rarely recorded throughout geographic range.

Remarks Sanderson (1939) reported that 'these bats were often mistaken for swallows, amongst which they fly in broad daylight from ca. 4 o'clock onwards, high above the forest trees', which were over 30 m high.

Conservation IUCN Category: Least Concern.

Major threats: loss and degradation of lowland rainforest. Population trend: not known. Recorded from only a few scattered localities but

probably very difficult to sample even if common. However, could be more threatened than this assessment suggests.

Glauconycteris curryae CURRY'S BUTTERFLY BAT

Fr. *Glauconyctère de Curry*; Ger. *Currys Schmetterlingsfledermaus*

Glauconycteris curryae Eger and Schlitter, 2001. Acta Chiropterologica 3: 2. 10 km W Bipindi (03° 05' N, 10° 25' E), at ca. 300 m, Cameroon.

Taxonomy Originally *Glauconycteris curryi* but the spelling was emended to *curryae* (Eger 2001). Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (11–12 mm) and rounded; wings dark brown (not conspicuously reticulated); dorsal pelage medium to dark brown, no shoulder-spot, no dorsal flank-stripe; tibia 14–16 mm; inner upper incisor strongly bicuspid. Sexes similar. Pelage dense; length at shoulder 7 mm. Dorsal pelage umber brown to sepia brown or reddish-brown; head and shoulders slightly paler than rump; hairs conspicuously tricoloured (cf. *G. beatrix*), basal half blackish-brown, followed by a narrow band of pinkish-buff, and a narrow terminal band of umber brown, sepia brown or reddish-brown. Ventral pelage paler. Head high-domed; muzzle short, broad and flattish. Ears of medium length for a *Glauconycteris*; inner margin semi-circular with rounded lobe at base; outer margin flattened, connecting with well-developed fleshy lobe on lower lip near corner of mouth. Tragus with tip rounded, inner margin straight, posterior margin straight with triangular lobe at base (Figure 124a). Wings and interfemoral membrane dark brown, not reticulated. Tibia short for this genus (14–16 mm). Tail length ca. equal to HB or slightly shorter.

Skull small and profile of forehead region (viewed laterally) strongly concave for a *Glauconycteris*. Inner upper incisor strongly bicuspid with secondary cusp ca. one-third to half the height of the main cusp. Lower incisors typically tricuspid, not crowded.

Glauconycteris curryae

Geographic Variation None.

Similar Species Three other *Glauconycteris* have dark wings and no dorsal flank-stripe:

Glauconycteris beatrix. Dorsal pelage dark sepia brown; hairs bicoloured. No dorsal markings (except shoulder-spot very rarely). Tibia longer (18–21 mm). Frontal region of skull weakly concave.

G. humeralis. Dorsal pelage dark brown; hairs bicoloured. Shoulder-spot present (except rarely). Ears rounded. Tibia almost always longer (16–20 mm).

G. poensis (sometimes). Dorsal pelage medium to dark greyish-sepia brown or brownish-grey. Shoulder-spot and/or dorsal flank-stripe either conspicuous, faint or absent. Tibia usually longer (16–19 mm). Inner upper incisor weakly bicuspid.

Distribution Endemic to Africa. Known only from five localities in Cameroon (10 km W Bipindi, Kumba, Njombo R. [67 km W Ayos], 13 km S and 8 km E Amban, and Eseka) and one in DR Congo (Bumba Zone, Yalosemba) (Eger & Schlitter 2001). All are in the Rainforest BZ.

Habitat Rainforest. Has been recorded over a pool in a vast stand of bamboo near a river. Also recorded over pools and forest streams, and on the shore of a lake, in Rainforest BZ.

Abundance Uncertain. Only seven specimens and six localities known.

Remarks Nothing else is known about the biology of this species.

Conservation IUCN Category: Data Deficient.

Major threat thought to be destruction of forest habitat.

Measurements

Glauconycteris egeria BIBUNDI BUTTERFLY BAT

Fr. Glauconyctère de Bibundi; Ger. Bibundi Schmetterlingsfledermaus

Glauconycteris egeria Thomas, 1913. Ann. Mag. Nat. Hist., ser. 8, 11: 44. Bibundi, Western Province, Cameroon.

Taxonomy Synonyms: none. Chromosome number: not known.

Description A beautiful, very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (12–19 mm) and subquadrangular; wings dark brown (not conspicuously reticulated); dorsal pelage dark brown to almost black with conspicuous whitish dorsal flank-stripe; inner upper incisor strongly bicuspid. Sexes apparently similar in colour. Pelage soft, dense. Dorsal pelage dark brown to almost black; hairs blackish-brown with terminal third dark brown, or black. Thomas (1913a) did not describe any markings (but the pelage of the holotype is in very poor condition); however, conspicuous shoulder-spots and dorsal flank-stripes are present in eight specimens (AMNH, ROM), with skull characters matching those of the holotype of *G. egeria*. Ventral pelage same as dorsal pelage. Head comparatively large, high-domed; muzzle short, broad and flattish. Ears comparatively long and broad for a *Glauconycteris*, subquadrangular in outline (cf. rounded in other dark-winged *Glauconycteris*), dark brown with a conspicuously pale rim. Inner margin of ear with long, backward-pointing lobe at base; outer margin connecting with rather small fleshy lobe on lower lip near corner of mouth. Tragus as in Figure 124d. Eyes very small. Wings and interfemoral membrane dark brown without reticulation. Tibia short for this genus. Tail ca. equal in length to HB.

Skull small and profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris*. Inner upper incisor long, strongly bicuspid with cusps ca. equal in size; the secondary cusp is near tip in holotype (Thomas 1913a). Inner upper incisor minute. Lower incisors tricuspid, not markedly crowded.

Geographic Variation No subspecies recognized. Dorsal pelage almost pure black in Uganda, but sepia brown in Cameroon (J. Eger pers. comm.).

Similar Species Two other *Glauconycteris* have dark wings and a dorsal flank-stripe:

Glauconycteris alboguttata. Dorsal pelage sepia brown with shoulder-spot as well as dorsal flank-stripe. Ears rounded, pale brown with paler rim. Inner upper incisors weakly bicuspid but secondary cusp small although clearly visible.

G. poensis (sometimes). Dorsal pelage medium to dark greyish sepia brown or brownish-grey; shoulder-spot and/or dorsal flank-stripe either conspicuous, faint or absent. Ears rounded. Inner upper incisor weakly bicuspid, cusps unequal in size.

Distribution Endemic to Africa. Known only from two areas in the Rainforest BZ (Bibundi and Buea in Cameroon [Thomas 1913a, ROM] and Dzanga-Sangha in Central African Republic [Lunde *et al.* 2001]), and one in the Eastern Rainforest–Savanna Mosaic (Budongo

Glauconycteris egeria

Forest, Uganda [ROM]). The identity of the specimens from Central African Republic reported as *Glauconycteris* cf. *egeria*, has since been confirmed by J. Eger (pers. comm.).

Habitat Rainforest. In Uganda, recorded over a swamp in rainforest, at ca. 1200 m.

Abundance Uncertain. Very rare in collections (four from Cameroon, three from Central African Republic, four from Uganda).

Remarks In Dzanga-Sangha forest reserve in Central African Republic, two adult ♀♀ were mist-netted within a metre of each other at the edge of a clearing in dense forest, and a ♂ was mist-netted along a road through the forest (Lunde *et al.* 2001). Kingdon's sketches labelled *G. superba* from Budongo Forest, Uganda (Kingdon 1974) do not resemble *G. superba*; instead they resemble *G. egeria*, which has been recorded and confirmed from this locality.

Conservation IUCN Category: Data Deficient.

Glauconycteris gleni GLEN'S BUTTERFLY BAT

Fr. Glauconyctère de Glen; Ger. Glens Schmetterlingsfledermaus

Glauconycteris gleni Peterson and Smith, 1973. R. Ont. Mus. Life Sci. Occas. Pap. 22: 3. Near Lomie, Cameroon.

Taxonomy Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (13–16 mm); wings white with dark brown reticulation on inner part of arm-wing and transverse lines across interfemoral membrane; dorsal pelage pale greyish-fawn without markings; inner upper incisors usually weakly bicuspid. Females on average slightly larger than ♂♂ in most body measurements. Pelage soft; extending over proximal third of interfemoral membrane; mid-dorsal hairs 7–9 mm. Dorsal pelage pale greyish-fawn with creamy sheen; hairs pale greyish-fawn or cream (both present) with dark brownish-grey base, an inconspicuous dark brown subterminal band and greyish-fawn or cream tip. No shoulder-spot or dorsal flank-stripe. Ventral pelage white to creamy-fawn; hairs pure white or creamy-fawn, with grey at base. Head high-domed; muzzle short, broad, flattish. Ears small for a vespertilionid but comparatively long for a *Glauconycteris*;

very pale brown, bluntly pointed; outer margin concave becoming convex near tip; inner margin convex. Wings semi-translucent white with dark brown pigmentation over wing-bones, hindlimbs and tail, and dark brown reticulation lines on arm-wing (sometimes only between elbow and ankle). Interfemoral membrane with dark brown transverse lines (Figure 125b). Tibia short for this genus (15–17 mm). Tail shorter than HB.

Skull moderately large and profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris*. Inner upper incisors usually weakly bicuspid; sometimes unicuspid. Lower incisors tricuspid or sometimes with four cusps; not crowded.

Geographic Variation None.

Similar Species Two other *Glauconycteris* have conspicuously reticulated wings:

Glauconycteris variegata. Dorsal pelage creamy-fawn. Flight-membranes

*Glauconycteris gleni*

pale yellowish-orange with dark brown reticulation on arm-wing, finger-wing and interfemoral membrane. Tibia longer, 18–21 mm.

G. machadoi. Dorsal pelage dark brown. Flight-membranes pale brown (? orange) with very dark reddish-brown reticulation on arm-wing, finger-wing and interfemoral membrane. Tibia longer, 20 mm.

Three other vespertilionids have white wings:

Pipistrellus rendalli and *P. tenuipinnis*. No brown reticulation lines on arm-wing. Outer margin of ear not reaching mouth; lower lip without lobe at posterior corner.

Scotoecus albofuscus. Only one upper incisor on each side. No brown reticulation lines on arm-wing. Penis long (ca. 9 mm).

Distribution Endemic to Africa. As yet, only known from the Rainforest BZ near Lomie, Cameroon and from the Eastern Rainforest–Savanna Mosaic at Malabigambo Forest in the Masaka District of Uganda (Peterson & Smith 1973).

Habitat Rainforest. No details recorded.

Abundance Uncertain. Very rarely recorded; only 18 specimens known when this species was described in 1973.

Remarks Nothing else appears to be known about the biology of this species.

Conservation IUCN Category: Data Deficient.

Only known with certainty from two localities but *Glauconycteris* are difficult to sample and this species might be more widely distributed than the records indicate. Population trend and threats not known.

Meredith Happold

Glauconycteris humeralis SPOTTED BUTTERFLY BAT

Fr. Glauconyctère tachetée; Ger. Gefleckte Schmetterlingsfledermaus

Glauconycteris humeralis J. A. Allen, 1917. Bull. Am. Mus. Nat. Hist. 37: 448. Medje, Orientale, DR Congo.

Taxonomy Synonyms: none. Considered to be a distinct species by Hayman *et al.* (1966) and Hayman & Hill (1971), but considered to be a subspecies of *G. beatrix* by some authors, including Koopman (1971, 1993), Peterson & Smith (1973) and Eger & Schlitter (2001). Differences in bacular morphology (Hill & Harrison 1987) indicate that *humeralis* probably is distinct (Heller *et al.* 1994). However, Heller *et al.* (1994) found that the baculum of a specimen from Irangi, DR Congo, is intermediate in shape and suggested that *humeralis* might merely represent a spotted form of *beatrix*. Tentatively treated here as a distinct species pending revision. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper

and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (6–12 mm) and rounded; wings dark brown (not conspicuously reticulated); dorsal pelage dark brown with a white shoulder-spot but no dorsal flank-stripe; tibia 16–20 mm; inner upper incisor strongly bicuspid with cusps ca. equal in size or with outer cusp smaller than inner cusp. Sexes apparently similar in colour and size. Pelage dense. Dorsal pelage dark sepia brown; hairs bicoloured (cf. *G. curryae*) with basal half blackish-brown, terminal half dark sepia brown. White shoulder-spot present (except perhaps rarely); hairs sometimes pure white, sometimes brown with white or yellowish-white at tip (Allen 1917a). Ventral pelage same as dorsal pelage. Head high-domed; muzzle short, broad and flattish. Ears yellowish-brown, medium-short for a *Glauconycteris*, very rounded;

inner margin with rounded lobe at base; outer margin connecting with well-developed, fleshy lobe on lower lip near corner of mouth. Tragus short, broad, anterior margin straight, posterior margin convex. Wings and interfemoral membrane dark brown, not reticulated; wing-bones pale brown dorsally and ventrally. Tibia of medium length for this genus (16–20 mm). Tail length greater than HB. Baculum (dorsal view) with basal portion unexpanded and unilobed, and distal portion lengthened to a short shaft (cf. *G. beatrix*) (Figure 128d; Hill & Harrison 1987).

Skull small and profile of forehead region (viewed laterally) moderately concave for a *Glauconycteris* (Figure 127b). Inner upper incisor described above. Lower incisors tricuspid or sometimes with four cusps; not crowded.

Geographic Variation None recorded.

Similar Species Three other *Glauconycteris* have dark wings and no dorsal flank-stripe:

Glauconycteris beatrix. Dorsal pelage dark brown without shoulder-spot (except rarely).

G. curryae. Dorsal pelage blackish-brown, sepia brown or reddish-brown; hairs conspicuously tricoloured. No shoulder-spot. Tibia usually shorter (14–16 mm).

G. poensis (sometimes). Dorsal pelage medium to dark greyish sepia brown or brownish-grey; hairs tricoloured. Shoulder-spot and/or dorsal flank-stripe either conspicuous, faint or absent. Inner upper incisor weakly bicuspid.

Distribution Endemic to Africa. Recorded from a part of the Rainforest BZ in DR Congo and extending into the Eastern Rainforest–Savanna Mosaic in Uganda and W Kenya (Rahm 1966, Heller *et al.* 1994, Eger & Schlitter 2001).

Habitat Rainforest. Recorded from Kakamega Forest in W Kenya, which has numerous grassy glades in extensive stands of tall evergreen forest.

Abundance Uncertain; seldom collected.

Remarks The holotype, an adult ♀, was one of four individuals ‘captured together in a bush’ (Lang & Chapin 1917b). A pregnant ♀ was recorded at 1–2° N (Avakubi) in DR Congo in Feb (Lang & Chapin 1917b).

Conservation IUCN Category: Data Deficient.

Glauconycteris kenyacola KENYACOLA BUTTERFLY BAT

Fr. Glauconyctère du Kenya; Ger. Kenya-Schmetterlingsfledermaus

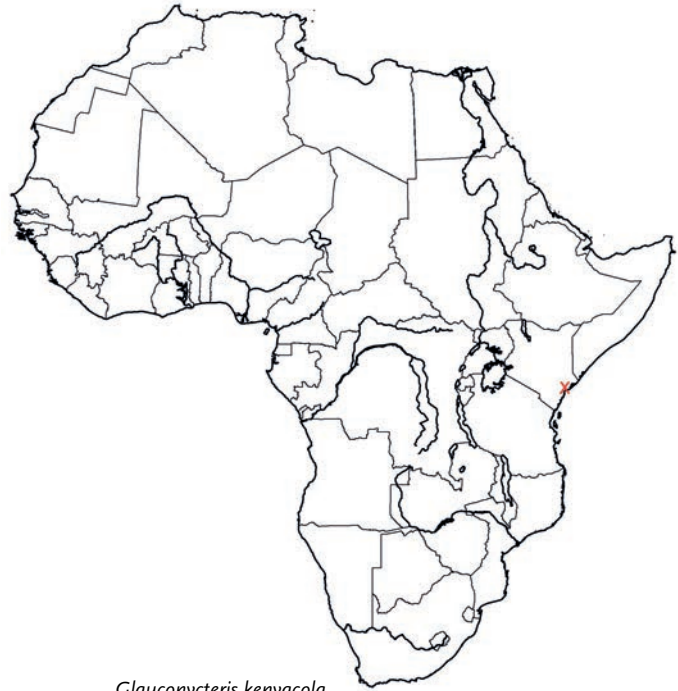

Glauconycteris kenyacola Peterson, 1982. Canadian J. Zool. 60: 2521. 8.5 km N Garsen, Coast Province, Kenya.**Taxonomy** Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (ca. 13 mm), moderately rounded; wings pale and faintly reticulated; dorsal pelage sepia brown with unique whitish markings on nose and around the bases of ears; inner upper incisor unicuspid. Pelage soft, dense. Dorsal pelage sepia brown, head and nape paler; hairs pale sepia brown merging into sepia brown at tip. No shoulder-spot or flank-line. Ventral pelage paler than dorsal pelage. Head with tuft of whitish hairs on nose, a thick band of white hairs extending from antitragus to base of ear, and whitish patches behind each ear. Ears of medium length for this genus, moderately rounded; inner margin with small subtriangular lobe at base; outer margin connecting with fleshy lobe on lower lip near corner of mouth. Eyes very small. Wings pale brownish-yellow with faint venation lines; dorsal surface with blackish-brown skin over bones of wing, legs and tail. Interfemoral membrane slightly darker than wings. Tibia long for this genus (20 mm). Tail equal in length to HB.

Skull small and profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris*. Four upper and five lower cheekteeth and two upper incisors on each side. Inner upper incisors unicuspid but with slight, posterior, blade-like ridge. Lower incisors tricuspid, not markedly crowded.

Geographic Variation None.**Similar Species** Only one other *Glauconycteris* has pale wings without conspicuous reticulation:

Glauconycteris argentata. Dorsal pelage pale golden-fawn or darker and greyer; no shoulder-spot; dorsal flank-stripe present but sometimes indistinct. No whitish markings on nose or base of each ear.

Distribution Endemic to Africa. Known only from the type locality in the Coastal Forest Mosaic BZ, in E Kenya.**Habitat** Peterson (1982) speculates that *G. kenyacola* may be restricted to the lower coastal plains of Kenya and adjacent regions. No other details are available.**Abundance** Uncertain. Only one individual known.**Remarks** Nothing else appears to be known about this species.*Glauconycteris kenyacola***Conservation** IUCN Category: Data Deficient.**Measurements***Glauconycteris kenyacola*

***Glauconycteris machadoi* MACHADO'S BUTTERFLY BAT**

Fr. Glauconyctère de Machado; Ger. Machados Schmetterlingsfledermaus

Glauconycteris machadoi Hayman, 1963. Comp. Diamantes de Angola, Ser. Cult. 1963: 107. Lac Calundo, Angola.

Taxonomy Synonyms: none. Often considered to be a subspecies of *G. variegata*, but given specific status by Crawford-Cabral (1986), Hayman & Hill (1971) and Peterson & Smith (1973). Koopman (1971) suggested that the only known specimen might be a melanistic mutant of *G. variegata*, or a representative of a localized melanistic population almost surrounded by the typical pale form. Tentatively treated here as a distinct species, pending further information, including the extent of normal variation in colour of *G. variegata*, molecular information for both forms, and whether or not there is an extant population of the dark coloured form that differs from *G. variegata* in other ways besides colour. Chromosome number: not known.

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (ca. 13 mm), rounded; all flight-membranes conspicuously reticulated; dorsal pelage brown without markings. Pelage fluffy, silky; mid-dorsal hairs ca. 8 mm. Dorsal pelage medium-dark brown, becoming slightly paler on the neck, and distinctly darker on top of head and face; changes colour, like shot-silk, depending on angle of view; hairs dark brown with slightly paler base. Ventral pelage pale greyish-cream; chin, lips and throat suffused with pale greyish-brown. Ears rounded; outer margin connecting with fleshy lobe near corner of mouth; inner margin – no data. Tragus as in *G. variegata*. Eyes very small. Wings and interfemoral membrane translucent, pale brown with very dark reddish-brown pigment outlining the wing-bones and venation (i.e. conspicuously reticulated), but the specimen is preserved as a dry skin and, in life, the flight-membranes may have been orange. Tibia long for this genus (20 mm). Skull and dentition as in *G. variegata*.

Geographic Variation None.

Similar Species Two other *Glauconycteris* have conspicuously reticulated wings:

Glauconycteris variegata. Dorsal pelage creamy-fawn. Flight-membranes pale yellowish-orange with dark brown reticulation on arm-wing, finger-wing and interfemoral membrane. Otherwise similar.

G. gleni. Dorsal pelage pale brown. Wings semi-translucent white with dark brown reticulation on inner part of arm-wing, and dark brown transverse lines across interfemoral membrane. Tibia shorter (15–17 mm).

Distribution Endemic to Africa. Known only from type locality in the Zambezian Woodland BZ in Angola.

Habitat The type locality is in wetter miombo woodland dominated by *Brachystegia* and *Julbernardia*.

Glauconycteris machadoi

Abundance Known from only one specimen.

Remarks The holotype was collected in a house. Nothing else is known about this species.

Conservation IUCN Category: Data Deficient.

Glauconycteris poensis ABO BUTTERFLY BAT

Fr. Glauconyctère d'Abo; Ger. Abo Schmetterlingsfledermaus

Glauconycteris poensis (Gray, 1842). Ann. Mag. Nat. Hist., ser. 1, 10: 258. Abo (lower Niger R.), Nigeria.

Taxonomy Originally *Kerivoula poensis*. Synonyms: *kraussii*. Subspecies: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated; short for a vespertilionid (9–13 mm), rounded; wings dark brown (not conspicuously reticulated); dorsal pelage greyish-brown or brownish-grey with or without shoulder-spot and/or dorsal flank-stripe; tibia 16–19 mm; inner upper incisors weakly bicuspid. Sexes similar in colour; ♀♀ on average slightly larger in body measurements than ♂♂. Pelage dense, soft; mid-dorsal hairs 5–7 mm. Dorsal pelage medium to dark greyish-sepia brown or brownish-grey; hairs tricoloured with basal third dark grey, middle third pale greyish-brown and terminal third medium to dark greyish-sepia or brownish-grey, sometimes with sandy tip. Head and shoulders sometimes paler. Shoulder-spot and dorsal flank-stripe markings very variable: one or both may be present, on one or both sides and, if present, they may be conspicuous to very faint. Shoulder-spot and flank-stripe may be separate or joined. Ventral pelage same as dorsal pelage; sometimes paler on throat. Pattern variation in individuals from Sierra Leone is described by Hayman & Jones (1950). Head high-domed; muzzle short, broad, flattish. Ears rounded; inner margin with moderately long, backward-pointing lobe at base; outer margin connecting with fleshy lobe on lower lip near corner of mouth. Eyes very small. Wings and interfemoral membrane dark brown with faint venation lines, especially near body. Postcalcareal lobe: no information. Tibia of medium length for this genus. Tail shorter than HB.

*Glauconycteris poensis*

Skull (Figure 124) small and profile of forehead region (viewed laterally) strongly concave for a *Glauconycteris*. Upper inner incisor weakly bicuspid with unequal cusps. Lower incisors tricuspid, sometimes slightly crowded.

Geographic Variation No subspecies recognized (Koopman 1994). No other information.

Similar Species Two other *Glauconycteris* have dark wings and a dorsal flank-stripe:

Glauconycteris albofasciata. Dorsal pelage sepia brown; hairs tricoloured. Shoulder-spot and dorsal flank-stripe present but sometimes faint.

G. egeria. Dorsal pelage dark brown or almost black with conspicuous whitish dorsal flank-stripe but no shoulder-spot. Ears subquadrangular, dark brown with conspicuously pale rim. Inner upper incisor strongly bicuspid, cusps ca. equal in size.

Three other species are similar to individuals of *G. poensis* which lack a dorsal flank-stripe:

G. beatrix. Dorsal pelage dark sepia brown; hairs bicoloured. No dorsal markings (except shoulder-spot very rarely). Tibia often longer (19.4 [18–21] mm). Inner upper incisor strongly bicuspid.

G. humeralis. Dorsal pelage dark sepia brown; hairs bicoloured. Shoulder-spot present (except rarely). Inner upper incisor strongly bicuspid.

G. curryae. Dorsal pelage blackish-brown, sepia brown or reddish-brown; head and shoulders slightly paler than rump. No dorsal markings. Tibia almost always shorter (14–16 mm). Inner upper incisor strongly bicuspid.

Distribution Endemic to Africa. Recorded from the Rainforest BZ and marginally from the Northern Rainforest–Savanna Mosaic from Sierra Leone to Cameroon and Bioko I., with isolated records near the boundary of the Sudan Savanna and Guinea Savanna BZs of Senegal (Adam & Hubert 1972), from the Rainforest BZ in DR Congo (Hayman *et al.* 1966) and perhaps from the Somalia–Masai Bushland BZ in Tanzania. Koopman (1971) refers to a specimen from Tanzania in BMNH (presumably 1902.11.5.3 from Guni R., Kilimanjaro): the identity of this specimen has not been confirmed and, because the locality is remote from other records, it is mapped as a question mark. A record from Marangu, Kilimanjaro, Tanzania (Uchikawa 1991) is most likely to represent *G. variegata* (Grimshaw *et al.* 1997). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Rainforest except for one record in Saboya Forest Reserve, near the Guinea and Sudan Savanna boundary in Senegal (Adam & Hubert 1972), and the dubious records from Tanzania (see Distribution). Recorded from primary forest in a sacred grove

surrounded by farmland on the Accra Plain of Ghana (Decher 1997). Found in rainforests and cocoa plantations, up to 1300 m on Bioko I. (Juste & Ibáñez 1994). Found in swamp forest in Taï N. P., Côte d'Ivoire (Fahr & Kalko 2011).

Abundance Uncertain. Uncommon in collections. Apparently common on Bioko I. (Juste & Ibáñez 1994).

Remarks By day, has been found, singly, in small holes in trees and clinging to stems of banana plants. Also found in groups of up to nine, clinging in a row, head to tail, along the leaflets of the fronds of Coconut Palms and Oil Palms in Sierra Leone (T. S. Jones in Grubb *et al.* 1998), and some were found in buildings (Rosevear 1965). A pair (♂ and ♀) were found inside a dead Cottonwood *Ceiba pentandra* (Jeffrey 1975).

Predators, Parasites and Diseases Ectoparasites include a flea *Lagaropsylla duodecima* (Siphonaptera: Ischnopsyllidae) (Beaucournu & Kock 1989).

Conservation IUCN Category: Least Concern.

Glauconycteris superba PIED BUTTERFLY BAT (SUPERB BUTTERFLY BAT)

Fr. Glauconyctère pie; Ger. Schwarzweiße Schmetterlingsfledermaus

Glauconycteris superba Hayman, 1939. Ann. Mag. Nat. Hist., ser. 11, 3: 219. Pawa, ca. 45 km ENE Medje, Ituri District, DR Congo.

Taxonomy Synonyms: *sheila*. Subspecies: none. Chromosome number: not known.

Description Small microbat (spectacularly black and white) without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (ca. 13 mm), subquadrangular; wings blackish (not conspicuously reticulated); dorsal pelage black, strikingly marked with white spots and stripes including three spots on the head; rostrum elongated and flattened (cf. other *Glauconycteris*). Medium-sized for a vespertilionid and the largest *Glauconycteris*. Sexual dimorphism: no information. Pelage dense, soft; mid-dorsal hairs 6–7 mm. Dorsal pelage black with white markings comprising one spot on the nose and two on forehead next to each ear, a backward-pointing subtriangular band on each side of mid-dorsal line (from shoulder-blade to mid-back), a narrow dorsal flank-stripe on each side, and either three spots in a row or one short line on each shoulder (Figure 126d–f). Ventral pelage with broad white band across throat, extending laterally to shoulders and then along each side of belly to anal region, leaving chin, flanks and mid-ventral area black. Dorsal and ventral hairs reddish to dark brown with black tip, or pure white. Ears long for the genus, subquadrangular. Tragus very broad, posterior margin distinctly curved with small basal lobule (Figure 124f). Wing-membranes dorsally blackish and without reticulation, ventrally with pale reticulation. Interfemoral membrane dorsally blackish, ventrally pale grey. Elbows, knees and ankles either black or pale. Tibia long for this genus (21 mm). Tail ca. 79% of HB.

Skull comparatively very large and robust for a *Glauconycteris*; profile of forehead region (viewed laterally) strongly concave (Figure

127a). Braincase high; sagittal crest weakly developed; lambdoid crest moderately developed. Rostrum conspicuously flattened and (viewed laterally) forming a sharp angle with braincase in frontal region. Inner upper incisor unicuspid. Lower incisors tricuspid (some with trace of fourth cusp) and crowded.

Geographic Variation Based on differences in colour pattern, Hayman (1946b) described *sheila* as a subspecies, but Rosevear (1965) suggested that pattern is possibly as variable in *G. superba* as in other *Glauconycteris* species, that the pattern described for *sheila* is not necessarily restricted to West Africa, and that the validity of *sheila* as a subspecies is dubious.

Similar Species None. No other *Glauconycteris* has conspicuous white markings on its head and ventral pelage.

Distribution Endemic to Africa. Known from only three localities in the Rainforest BZ (Western and East Central Regions). The record from Côte d'Ivoire, examined by Peterson & Smith (1973), is based on a single specimen from Matonguiné supposedly in the RMCA collection (J. Eger pers. comm.), which could not be found upon request (W. Van Neer pers. comm.). The record by Kingdon (1974) from Budongo Forest, Uganda, is disregarded here as the specimen illustrated by the author apparently does not represent *G. superba*.

Habitat The records from Matonguiné, Côte d'Ivoire (07° 18' N, 08° 04' W) and Oda, Ghana (05° 55' N, 00° 59' W) are located in the region of semi-deciduous forest at the periphery of evergreen lowland rainforest at ca. 360 m and 190 m, respectively. The type

*Glauconycteris superba*

locality – Pawa, DR Congo (02° 32' N, 27° 42' E) – is situated in the NE Congolian lowland rainforest at ca. 700 m.

Abundance Apparently very rare and local; only one specimen known from each of three localities.

Remarks The specimen from Ghana was found on the ground but still alive by G. S. Cansdale. No other information.

Conservation IUCN Category: Least Concern.

Apparently very rare, only three localities and specimens known; area of occupancy very restricted. The specimens originated from areas that are nowadays heavily degraded and fragmented, especially in West Africa. Major threat: loss of habitat as result of logging and agriculture. Population size unknown but population trend inferred to be declining. Based on this information, categorization as Least Concern seems very misleading: a threatened category or Data Deficient would be more appropriate.

Glauconycteris variegata VARIEGATED BUTTERFLY BAT

Fr. Glauconyctère papillon; Ger. Genetzte Schmetterlingsfledermaus

Glauconycteris variegata (Tomes, 1861). Proc. Zool. Soc. Lond. 1861: 36. Otjoro, Namibia.

Taxonomy Originally *Scotophilus variegata*. Synonyms: *papilio*, *phalaena*. Subspecies: two currently recognized. *Glauconycteris machadoi*, which is sometimes considered to be a melanistic subspecies or mutant of *G. variegata*, is tentatively treated here as a distinct species. Chromosome number (South Africa): 2n = 18; aFN = 32 (Rautenbach *et al.* 1993).

Description Beautiful, small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (11–14 mm); all flight-membranes conspicuously reticulated; dorsal pelage pale without markings. Sexes similar. Pelage dense, soft; mid-dorsal hairs 7–10 mm. Dorsal pelage pale creamy-buff to yellowish-fawn, sometimes becoming paler on head and neck; hairs pale creamy-buff or yellowish-fawn with paler base, or creamy-white with brown base and yellowish-fawn tip. Ventral pelage yellowish-cream to pure white, sometimes suffused with pale grey especially

on throat. Head high-domed; muzzle short, broad and flattish. Ears light brown; outer margin connecting with fleshy lobe near corner of mouth; inner margin with moderately long, backward-pointing lobe at base. Tragus with anterior margin straight, posterior margin convex with inconspicuous lobe at base (Figure 124g). Eyes very small. Wings and interfemoral membrane pale yellowish-orange with dark brown pigment outlining bones and venation (i.e. conspicuously reticulated) (Figure 125a). Tibia long for this genus (18–21 mm). Tail shorter than HB.

Skull moderately large and profile of forehead region (viewed laterally) weakly concave for a *Glauconycteris*. Upper incisor variable (unicuspid to strongly bicuspid with unequal cusps). Lower incisors tricuspid, crowded, at right-angles to line of jaw.

Geographic Variation Two subspecies are currently recognized (Hayman & Hill 1971, Koopman 1975, Simmons 2005), but their validity is uncertain:

- G. v. phalaena*: SC Sudan, Somalia. Dentition comparatively less massive. Dorsal pelage paler (Thomas 1915b).
G. v. variegata: remainder of geographic range (including NE Ethiopia according to Hill & Morris [1971]). Canines, premolars and molars comparatively massive.

Koopman (1975) commented that the distribution of *G. variegata* and the subspecies *phalaena* (if valid) in the region of the Sudan is imperfectly known.

Similar Species Two other *Glauconycteris* have conspicuously reticulated wings:

- Glauconycteris machadoi*. Dorsal pelage dark brown. Flight-membranes pale brown (? orange) with very dark reddish-brown reticulation on arm-wing, finger-wing and interfemoral membrane. Otherwise similar.
G. gleni. Dorsal pelage pale brown. Wings semi-translucent white with dark brown reticulation on inner part of arm-wing, and dark brown transverse lines across interfemoral membrane. Tibia shorter (15–17 mm).

Distribution Endemic to Africa. Widespread south of the Sahara, mainly in the Sudan Savanna and Guinea Savanna BZs, the Rainforest–Savanna Mosaics and the Somalia–Masai Bushland, Coastal Forest Mosaic and Zambezian Woodland BZs. Also recorded in the Afromontane–Afroalpine BZ in some localities, and there is one record in the Rainforest BZ. Senegal to Ethiopia and Somalia, and southwards to N Namibia, N Botswana and N South Africa (but not yet recorded from all countries within this area). Mapped from country checklists (see order Chiroptera), other literature and museum records.

Habitat Mainly savanna habitats including open woodland savannas and open bush country (e.g. Lang & Chapin 1917b, Smithers 1983,

Happold & Happold 1987, Obrist *et al.* 1989, Grubb *et al.* 1998). Has been recorded within the rainforest zone, but probably where the forest has been destroyed (Rosevear 1965). In dry country in Zimbabwe and Malawi, often associated with riverine woodland. Has been recorded over streams and pools. In southern Africa, not found in forests according to Smithers (1983), but more recently a specimen was mist-netted in a public picnic ground within dense forest in KwaZulu–Natal (Taylor, P. 1998).

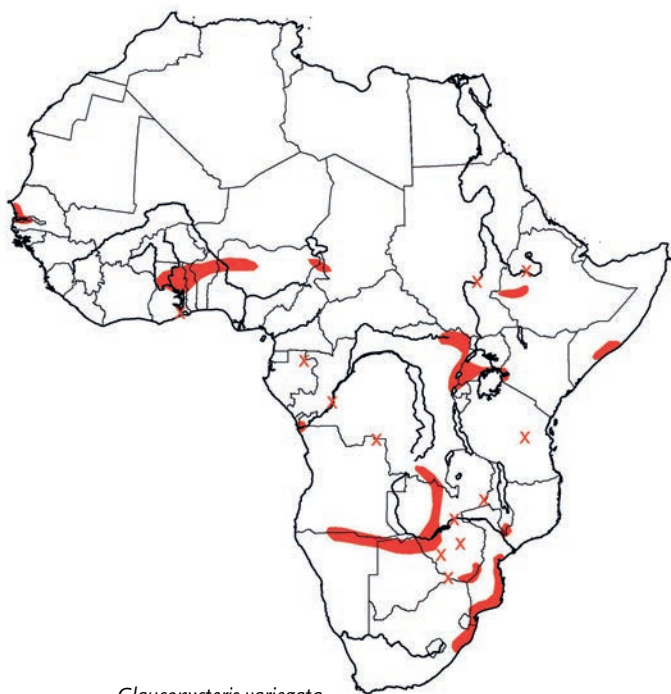

Abundance Rarely collected and considered rare throughout its geographic range, but its habits make this species difficult to find and capture.

Adaptations Aspect ratio low; wing-loading low to very low; wing-tip comparatively long and pointed (Obrist *et al.* 1989, M. Happold unpubl.). These data imply efficient low-speed flight as well as being able to fly moderately fast. Manoeuvrability moderate. Turns by banking (minimum radius just under 50 cm) and sometimes by stalling-and-twisting; individuals could fly across a 1×1×1 m enclosure but were unable to fly more than one circuit/flight (2 bats, 10 flights each). Can take off from ground. By day, roosts mainly in trees, hanging within dense clusters of leaves (Lang & Chapin 1917b, Pienaar *et al.* 1980, McLellan 1986, Obrist *et al.* 1989). Because the reticulated wings resemble dead leaves, roosting bats are very difficult to see unless they move. Has also been found hiding in the thatch of abandoned huts (Lang & Chapin 1917b). In Zimbabwe, one group returned to roost in the same cluster of leaves for several consecutive days, despite being disturbed every day (Obrist *et al.* 1989); this roost was in the underside of the canopy of a *Trichilia emetica* tree, ca. 7.5 m above ground. On overcast days, individuals sometimes leave their roosts up to two hours before sunset (Lang & Chapin 1917b).

Foraging and Food Forages, by moderately fast-hawking, high above the ground (e.g. 18 m) in uncluttered environments (Lang & Chapin 1917b), but can also forage close to clutter, such as between trees (Taylor 2000, M. Happold unpubl.). Lang & Chapin (1917b) wrote: ‘They fluttered swiftly, now and then increasing their speed with such spontaneous ease that one hardly noticed the quickened beating of their wings as they gathered their tiny insect prey.’ Stomach contents and faeces of perhaps no more than three bats contained moths (Kingdon 1974, Fenton *et al.* 1977).

Echolocation Search-phase call-shape (Zimbabwe) smooth steep–shallow FM. Start-frequency (mean ± S.D.) 53.4 ± 7.7 kHz; end-frequency 33.7 ± 1.7 kHz; peak-frequency 37.7 ± 1.6 kHz; bandwidth 19.7 ± 7.7 kHz; call-duration 5.3 ± 1.4 ms (211 calls, two bats foraging; Obrist *et al.* 1989). Approach-phase calls are shorter and broader in bandwidth.

Social and Reproductive Behaviour Has been found roosting singly, in pairs and in small groups of three to ca. 12. One group of six adults comprised four ♀♀ with neonates and two not sexed (Obrist *et al.* 1989). A group of eight adults, found roosting on a low branch of a mango tree in Sudan, included a ♂ and two ♀♀ (others not sexed) (McLellan 1986).

Glauconycteris variegata

Reproduction and Population Structure Litter-size: one or two; single foetuses ($n = 5$), twin foetuses ($n = 1$), ♀ ♀ with one neonate ($n = 4$) (Lang & Chapin 1917b, Smithers & Wilson 1979, Obrist *et al.* 1989, BMNH). Reproductive chronology: not known. At 3–4°N in NE DR Congo, 3 of 10 ♀ ♀ were pregnant in Mar; parturition predicted to occur in Mar–Apr at which time the young could take refuge in low bushes and vegetation newly in leaf after the annual dry season fires in Dec and Jan had left them completely bare (Lang & Chapin 1917b). At 01° 17'S (Nairobi, Kenya), a lactating ♀ was recorded in Apr (ROM). At 16–20°S in Zimbabwe, pregnancies were recorded in Aug (Smithers & Wilson 1979) and births in Nov (Obrist *et al.* 1989), but there are no data for other months. The reproductive chronology cannot be determined from these data because there are no year-round observations at any of these localities.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

GENUS *Laephotis* African Long-eared Bats

Laephotis Thomas, 1901. Ann. Mag. Nat. Hist., ser. 7, 7: 460. Type species: *Laephotis wintoni* Thomas, 1901.

Laephotis wintoni with ears fully erect.

A small genus with four species, endemic to Africa south of the Sahara. Diagnostic combination of characters: four upper and five lower cheekteeth and two upper incisors on each side; ears moderately long and wide for an African vespertilionid (15–25 mm) but relatively larger than in any other sub-Saharan genus (ca. half length of FA or a little longer); ears not joined at base (cf. *Plecotus*); outer margin of ear not reaching mouth; no body pattern; wings not reticulated; head slightly flattened; dental formula: $^{2113}/_{3123} = 32$ (cf. *Otonycteris* but as in *Glauconycteris*, *Eptesicus*, some *Pipistrellus* and *Mimetillus*); see Table 21, p. 545. The upper and lower premolars are tall teeth, almost the same height as the canines, and this, together with toothwear on the canines, might account for the suggestion that the canines are

extremely reduced (Hayman & Hill 1971, Kingdon 1974). Selected characters of *Laephotis* are illustrated in Figure 129. Placed in tribe Vespertilionini by Hill & Harrison (1987) on basis of baculum morphology, and retained in that tribe by Simmons (2005).

Prior to Peterson's (1971c) and Setzer's (1971) revisions, this genus was considered monotypic with two subspecies. Peterson (1971c) introduced *wintoni* and *angolensis* as distinct species, while Setzer (1971) described two further species, *namibensis* and *botswanae*. However, inter-specific relations remain unresolved largely because specimens are few and in scattered collections (Kock & Howell 1988, Stanley & Kock 2004). Several specimens from South Africa were assigned to *L. wintoni* and *L. cf. wintoni* on the basis of multivariate analyses (Rautenbach & Nel 1978, Watson 1990a, Kearney & Taylor 1997). Given the distance of South African localities from other populations of *L. wintoni* in Kenya and Ethiopia, this identification was considered with some scepticism and not followed by Honacki *et al.* (1982) or Corbet & Hill (1991). Specimens described by Rautenbach & Nel (1978) were subsequently provisionally placed with *L. namibensis* (Skinner & Smithers 1990). Kock & Howell (1988) and Stanley & Kock (2004) identified several cases where specimens identified as *L. angolensis* have been re-identified as *L. botswanae* or *L. cf. angolensis*. Morphometric analyses that included palatal and post-palatal measurements (Kearney & Seamark 2005) allowed the distinction of *L. botswanae* and *L. cf. angolensis* from other species of *Laephotis*, and suggested the assignment of specimens from KwaZulu–Natal previously identified as *L. cf. wintoni* to *L. botswanae*. However, the distinction between *L. wintoni* and *L. namibensis* was not confirmed and still remains to be clarified (Kearney & Seamark 2005).

In his initial description of the genus *Laephotis*, Thomas (1901) suggested the genus was most closely allied to *Vespertilio*. Tate (1942)

Figure 129. *Laephotis*. (a) Flight membranes, and bones of wing, hindlimb and tail of *L. botswanae*. (b) Left ear of *L. botswanae* (frontal view). Tragi of (c) *L. botswanae*, (d) *L. namibensis* and (e) *L. wintoni* (scale = 2mm). (f), (g) and (h) Lateral, dorsal and ventral views of skull of *L. wintoni* (holotype, BMNH 1.5.6.5). pal = palatal length as defined by Kearney & Seamark (2005), see Table 24.

considered *Laephotis* the closest relative of the Neotropical big-eared genus, *Histiotus*, which in turn was considered an offshoot of *Eptesicus*. However, the ears in *Laephotis* are not as greatly enlarged as in *Histiotus*, nor are they connected across the forehead (Hayman & Hill 1971). On geographic grounds, Williams & Mares (1978) doubted the association with *Histiotus*. Hill (1974a) considered *Laephotis* an independent offshoot of *Eptesicus*.

A fairly wide range of biotic zones and habitats are exploited by this genus: the Somalia–Masai Bushland, Zambezi Woodland, the Southern Rainforest–Savanna Mosaic (marginally), Afromontane–Afroalpine, Highveld, South-West Arid and South-West Cape BZs.

The four species can be identified from the information in Table 24.

Laephotis angolensis ANGOLAN LONG-EARED BAT

Fr. Oreillard d'Angola; Ger. Angola-Langohrfledermaus

Laephotis angolensis Monard, 1935. Archos. Mus. Bocage 6: 45. Tyihumbwe, 15 km west of Dala, Angola.

Taxonomy Synonyms: none. Described, as a distinct species, from a single specimen, ♀ with damaged skull, but subsequently considered a subspecies of *L. wintoni* (Ellerman *et al.* 1953, Hayman & Hill 1971). Although currently treated as a distinct species, the relationship between *L. angolensis* and *L. botswanae* is obscure, partly because specimens of *L. angolensis* are so scarce that variation within this form cannot be assessed. Peterson (1973) suggests that *L. botswanae* may prove to be a larger, southern race of *L. angolensis*. However, both species occur together in S DR Congo (Setzer 1971). Several specimens originally considered to represent *L. w. angolensis* were later reassigned to *L. botswanae* (Smithers 1971, Hill 1974a). Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, of medium length for a vespertilionid (15–18 mm) and of medium relative length (45–46% of FA, $n = 2$), not joined at base; GLS: 13.7–13.8 mm. A very poorly known species. Sexual dimorphism: no information. Mid-dorsal hairs ca. 7 mm. Dorsal pelage yellowish-brown to reddish-brown; hairs distinctly bicoloured, basal 5 mm blackish-brown, terminal 2 mm yellowish-brown or reddish-brown. Ventral pelage pale grey on chin, paler on throat, becoming cream or white in pelvic region; hairs (except pelvic region) blackish-brown with pale grey, cream or white tip. Ventral hairs in pelvic region pure white. The naked skin on muzzle and around eyes is dark brown. Ears dark brown, roughly triangular but very elongated; tip rounded; inner margins almost meeting on forehead but not joined. Ears may be held erect above head or (when resting) held sideways at right-angles to head. Tragus with notch at base of posterior margin as in *L. botswanae*, but diagnostic differences between the tragi of these species, if present, are not known. Wings dark brown; arm-wing with whitish hind-border. Interfemoral membrane medium-brown, more translucent.

Skull (as in all *Laephotis* spp.) with braincase slightly flattened; rostrum rather narrow; zygomatic arches slender; no sagittal crest; lambdoid crest weakly developed. Skull apparently shorter and usually narrower than in other *Laephotis* but data very limited (GLS: 13.7–13.8 mm; GWS: 6.7, 8.1 mm, $n = 2$). Palatal length 6.1, 6.2 mm ($n = 2$) (cf. >6.4 mm in *L. botswanae* and *L. wintoni*) (Hill 1974a).

Geographic Variation None.

Similar Species Not easily distinguished from other *Laephotis*, and relationship with *L. botswanae* is uncertain.

Laephotis botswanae. Ventral pelage paler. Tragus broader; posterior margin more angular. Skull longer (GLS: 14.1–15.5 mm) and usually broader (GWS: 8.0–8.8 mm). Rostrum slightly longer and broader, palate longer (Hill 1974a).

*Laephotis angolensis*

L. wintoni. Forearm longer (37–41 mm). Ears longer (21–24 mm) and broader. Skull longer and broader (GLS: 15.6–16.3 mm, GWS: 8.8–9.5 mm, C–M³: 5.1–5.3 mm).

L. namibensis. Forearm usually longer 37.8 (36–40 mm). Ears longer (22–25 mm). Skull larger (GLS: 16.1–17.0 mm, GWS: 8.4–9.2 mm, C–M³: 4.8–5.4 mm).

Distribution Endemic to Africa. Apparently restricted to the Zambezian Woodland BZ and the southern fringe of the Southern Rainforest–Savanna Mosaic. Recorded from Angola and SE DR Congo (Peterson 1971c, Setzer 1971, Hill 1974a).

Habitat No details available.

Abundance Rare.

Remarks Nothing else is known about the habits of this species. **Predators, Parasites and Diseases** Ectoparasites recorded include a bed-bug *Cacodmus villosus* (Hemiptera: Cimicidae), a tick *Rhipicephalus simus* (Acari: Ixodidae) and mites *Spinturnix walkeri* (Acari: Spinturnicidae), *Steatonyssus* sp. (Acari: Macronyssidae) (Anciaux de Faveaux 1984), although the information is uncertain because the identity of the host still needs to be confirmed.

Conservation IUCN Category: Data Deficient.

Laephotis botswanae BOTSWANAN LONG-EARED BAT

Fr. Oreillard du Botswana; Ger. Botswana-Langohrfledermaus

Laephotis botswanae Setzer, 1971. Proc. Biol. Soc. Washington 84: 260, 263. 80 km west and 19 km south of Shakawe, Botswana.

Taxonomy Synonyms: none. The distinction between *L. botswanae* and *L. angolensis* remains obscure and many specimens originally described as *L. angolensis* have been reassigned to *L. botswanae* (Hill 1974a, Ansell 1978) or remain of unsettled identity (Fenton & Bell 1981, Fenton 1985). Both species occur together in S DR Congo (Setzer 1971), and Kock & Howell (1988) question the validity of the species status of *botswanae* because of this. Chromosome number (South Africa): 2n = 34; aFN = 50 (as in *L. namibensis* and *L. wintoni* [Rautenbach *et al.* 1993]).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, of medium length for a vespertilionid (17–22 mm) and of medium relative length (44–64% of FA, n = 22); GLS: 14.1–15.5 mm. A poorly known species. Sexes similar. Pelage soft, slightly shaggy on rump; mid-dorsal hairs ca. 8 mm. Dorsal pelage reddish-brown, chocolate brown or pale brown; hairs distinctly bicoloured, basal 6 mm blackish-brown, terminal 2 mm reddish-brown, chocolate brown or pale brown. Ventral pelage creamy-brown on chin, paler on throat, becoming cream or white in pelvic region; hairs (except in pelvic region) with basal 4 mm blackish-brown, terminal 4 mm creamy-brown, cream or white. Hairs in pelvic region pure white. The naked skin on muzzle and around eyes is brown. Ears pale to medium brown, roughly triangular with broad base and rounded tip; reaching well beyond snout when laid forward; inner margins almost meeting on forehead, but not joined. Ears may be held erect above the head or (when resting) held horizontally at right-angles to head. Tragus as in Figure 129c. Wings dark brown; arm-wing usually with whitish hind-border; interfemoral membrane paler and more translucent.

Skull (as in all *Laephotis* spp.) with braincase slightly flattened; rostrum rather narrow; zygomatic arches slender; no sagittal crest; lambdoid crest weakly developed. Skull on average medium-short and of medium width for the genus (GLS: 14.4–15.5 mm; GWS: 8.0–8.8 mm). Palatal length 6.7 (6.2–7.3) mm, n = 21 (Kearney & Seamark 2005).

Geographic Variation No subspecies recognized. Pelage colour varies according to locality – the dorsal pelage of TM specimens from South Africa are reddish-brown, those from Zimbabwe are paler brown.

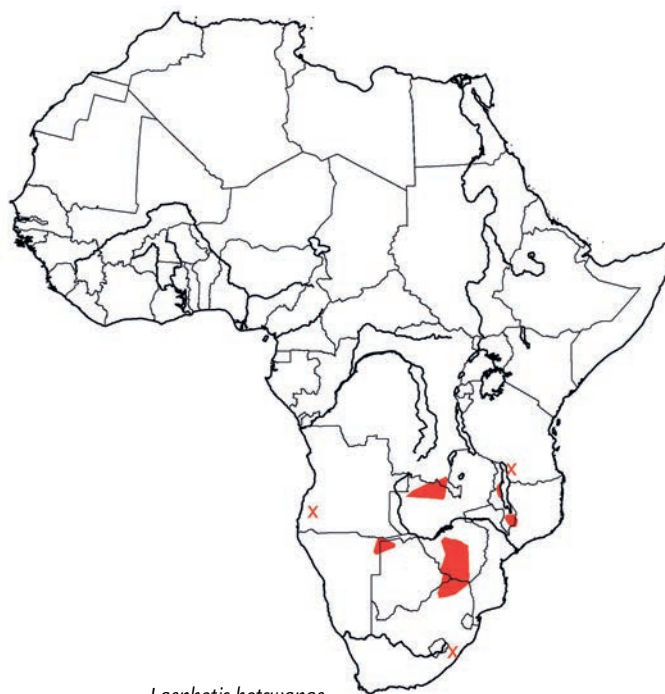

Similar Species Not easily distinguished from other *Laephotis*, and relationship with *L. angolensis* is uncertain.

Laephotis angolensis. Ventral pelage darker. Tragus narrower, posterior margin less angular. Skull shorter (GLS: 13.7–13.8 mm) and usually narrower (GWS: 6.7, 8.1 mm), but data very limited. Rostrum slightly shorter and narrower; palate shorter (Hill 1974a).

L. wintoni. Forearm on average longer (39.6 [37–41] mm). Skull usually larger (GLS: 16.0 [15.6–16.3] mm; C–M³: 5.2 [5.1–5.3] mm).

L. namibensis. Skull longer (GLS: 16.1–17.0 mm).

Distribution Endemic to Africa. Known from scattered localities in the Zambezian Woodland BZ and marginally in one part of the Kalahari Desert area in the South-West Arid BZ. Recorded from Angola, S DR Congo, S Tanzania, Zambia, Malawi, N Botswana, Zimbabwe, South Africa. The most southern record (see map) is

Laephotis botswanae

based on re-identified specimens from Hella-Hella (KwaZulu–Natal, South Africa): it extends the geographic range by ca. 658 km further south (Kearney & Seamark 2005).

Habitat Most specimens have been caught in mist-nets, usually over or close to water, in riverine woodland or woodland savanna. Their association with rocky outcrops has been noted in some localities (Herholdt 1989, Cotterill 1996a). In Malawi, recorded near streams, and lakes in montane and sub-montane evergreen forest at 1520–1700 m, from miombo woodland near sub-montane rainforest at 1350–1500 m, from mosaic of miombo woodland, farmland and riverine woodland near rocky hills, dams, streams and marshes at 1000 m, and in ornamental gardens in the town of Zomba (800–900 m), with rocky hills nearby (Happold & Happold 1997).

Abundance Rare in some parts of their distribution, although Herholdt (1989) and Happold & Happold (1997) have suggested it is not uncommon, but seldom caught at other localities. There was a marked change in numbers recorded in Malawi between a survey in 1984–85 with three specimens (Happold *et al.* 1987), and 1993–94 with 17 specimens (Happold & Happold 1997). Herholdt (1989) suggested that their being caught singly might indicate they are not easily captured in mist-nets. Numbers in museum collections are growing.

Adaptations Aspect ratio low; wing-loading very low (Malawi; M. Happold pers. comm.). Flight highly manoeuvrable; turns by banking (minimum radius <25 cm) and by stalling-and-twisting; individuals were able to sustain flight in a 1×1×1 m enclosure for up to three circuits/flight (6 bats, 10 flights each; M. Happold pers. comm.). Can take off from ground. Not easily able to climb or scuttle. A pair was found roosting under the bark of a broken limb of a tree (HSM specimen label written by W. F. H. Ansell); no other roosts known. Becomes torpid during day at ambient temperatures 21–24 °C. Predicted mean maximum urine concentration is medium (3745 mOsmol/kg); captive bats drank regularly every night (Happold & Happold 1980).

Foraging and Food Forages by slow-hawking. A light-tagged individual, released in an area with marshland, a large dam, some woodland and farmland, observed for 53 min, foraged mainly between 1–3 m over the marsh, making straight level traverses to and fro with some jerky zig-zagging and some wide circling, but no diving or swooping upwards or any other aerobatic manoeuvres; also foraged over tall grass in spaces between trees, and flew over a banana plantation; did not fly above other trees and did not forage over the open water (M. Happold pers. comm.). Fenton (1985) reported Coleoptera, Lepidoptera and Trichoptera in cool season diet of *Laephotis* in Zimbabwe, and Lepidoptera only in wet season; however, he was not sure if the bats represented *L. botswanae* or *L. angolensis* and this is still unresolved.

Echolocation Search-phase call-shape (Malawi) (a) steep FM/QCF (Figure 118a) and (b) smooth steep/shallow FM (six bats recorded as released, one tethered; M. Happold pers. comm.). (a) Start-frequency 60–72 kHz; end-frequency 29–33 kHz; peak-frequency 29–33 kHz; call-duration ca. 3–5 ms (155 calls). (b) Start-frequency 47–49 kHz; end-frequency 32–33 kHz; call-duration

7–8 ms (12 calls). Fenton & Bell (1981) reported calls from *Laephotis* of uncertain identity from Zimbabwe (see above) for which call-shape (based on one illustrated call) was angular steep/shallow FM; start-frequency 55 kHz; end-frequency 32 kHz; peak-frequency 33 kHz; maximum call-duration 5 ms. Although call-shapes differed, the peak-frequency was the same in calls from Malawi and Zimbabwe, suggesting that the bats in both localities represent *L. botswanae*.

Social and Reproductive Behaviour Very little information. Of 20 individuals sampled in Malawi, one post-lactating ♀ and one subadult ♂ were mist-netted together; one reproductively inactive ♀, one lactating ♀ and one ♂ with abdominal testes were caught in one mist-net at intervals of 15 min and 5 min respectively; and all others were caught singly on different dates and at different localities (M. Happold pers. comm.). All of four individuals mist-netted by Herholdt (1989) in the Waterberg area in the Limpopo Province of South Africa were caught singly.

Reproduction and Population Structure Litter-size: not known. Reproductive chronology not known (data inconclusive). At 15° 31' S (near Namadzi, Malawi), 2 of 3 adult ♀♀ were lactating and one was reproductively inactive in Dec; 2 of 2 were reproductively inactive in Jan; 2 of 2 were post-lactating in Feb; no data for other months (M. Happold pers. comm.). Two subadults were captured in Jan and Feb. These data suggest that ♀♀ might not reach sexual maturity until second year.

Predators, Parasites and Diseases A bed-bug *Cacodmus villosus* (Hemiptera: Cimicidae) has been recorded on *L. botswanae* from Huila, Angola, and found on *Laephotis* from S DR Congo, of which most of the host series have been identified as *L. botswanae*, although two specimens are considered to represent *L. cf. angolensis* (Stanley & Kock 2004).

Conservation IUCN Category: Least Concern.

***Laephotis namibensis* NAMIBIAN LONG-EARED BAT**

Fr. Oreillard de Namibie; Ger. Namibia-Langohrfledermaus

Laephotis namibensis Setzer, 1971. Proc. Biol. Soc. Washington 84: 259. Kuiseb River, Gobabeb, Namibia.

Taxonomy Synonyms: none. Two specimens from Algeria Forest, Cederberg, in the Western Cape of South Africa were identified as *L. wintoni* (on basis of multivariate statistics) by Rautenbach & Nel (1978), but they were subsequently re-identified as *L. namibensis* in Skinner & Smithers (1990). Three additional specimens caught at Algeria, two of which are in the South African Museum collection, confirm the occurrence of *L. namibensis* in South Africa. Chromosome number (Namibia): $2n = 34$; $aFN = 50$ (as in *L. botswanae* and *L. wintoni*) (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, of medium length for a vespertilionid (22–25 mm) and of medium relative length (54–65% of FA, $n = 11$); GLS: 16.1–17.0 mm. A poorly known species. Sexes similar. Pelage soft, slightly shaggy on rump; mid-dorsal hairs ca. 7 mm. Dorsal pelage creamy-brown or yellowish-brown; hairs distinctly bicoloured, basal 4 mm dark brown, terminal 3 mm creamy-brown or yellowish-brown. Ventral pelage (except in pelvic region) pale cream to whitish; hairs with basal 4 mm blackish-brown, terminal 3 mm pale cream or white. Hairs in pelvic region pure white. The naked skin on muzzle and around eyes is pale brown. Ears pale to medium-brown, roughly triangular but elongated; tip rounded; inner margins almost meeting on forehead but not joined. Ears may be held erect above the head or (when resting) held horizontally at right-angles to head. Tragus shape much like that of *L. botswanae* except that in *L. namibensis* the bulge above the basal, posterior notch extends further out, making the tragus much wider at that point (Figure 129d). Wings pale creamy-brown (when dorsal pelage is pale) or dark brown (when dorsal pelage is yellowish-brown); arm-wing usually with whitish hind-border. Interfemoral membrane paler and more translucent.

Skull (as in all *Laephotis* spp.) with braincase slightly flattened; rostrum rather narrow; zygomatic arches slender; no sagittal crest; lambdoid crest weakly developed. Skull on average long and wide for the genus (GLS: 16.1–17.0 mm; GWS: 8.4–9.2 mm). Palatal length: 8.0 (7.6–8.7) mm, $n = 10$ (Kearney & Seamark 2005).

Geographic Variation No subspecies are currently recognized. Specimens from Namibia have much paler pelage and flight-membranes than those from South Africa.

Similar Species Not easily distinguished from other *Laephotis*:

Laephotis angolensis. FA shorter (34.3 [32–36] mm). Ears shorter (15–18 mm) and narrower. Skull smaller (GLS: 13.7–13.8 mm; GWS: 6.7, 8.1 mm; C–M³: 4.3 mm).

L. botswanae. Skull shorter (GLS: 14.1–15.5 mm).

L. wintoni. Skull usually shorter (GLS: 15.6–16.3 mm). Dorsal pelage and wings apparently never creamy-brown (as far as is known).

Laephotis namibensis

Distribution Endemic to Africa. Found in the South-West Arid BZ (Namib Desert) and in the South-West Cape BZ. Recorded from Namibia (Gobabeb, Zwartmodder, Klein Aus, Helmeringshausen) and South Africa (Algeria Forest) (Setzer 1971, TM).

Habitat Arid, mountainous habitat, in close proximity to open water.

Abundance Rare.

Remarks Very little is known about this species. One individual was found under exfoliating rock (TM). The holotype and paratype were mist-netted over a waterhole in the bed of the Kuiseb R. near Namib Desert Research Station (Setzer 1971). Individuals from Algeria Forest were mist-netted as they flew along a water-course, close to the water surface, between 20:30 and 21:00h.

Conservation IUCN Category: Least Concern.

Categorized as such because most of its known range is within well-protected areas, there are no significant threats and its population is unlikely to be declining fast enough to qualify for listing in a more threatened category. Type locality (Gobabeb) is close to Namib Naukluft Park, which includes some of the Naukluftberge where this species probably roosts.

Laephotis wintoni DE WINTON'S LONG-EARED BAT

Fr. Oreillard de De Winton; Ger. De Wintons Langohrfledermaus

Laephotis wintoni Thomas, 1901. Ann. Mag. Nat. Hist., ser. 7, 7: 460. Kitui, 1150 m, Kenya.

Taxonomy Synonyms: none. South African specimens were assigned to *L. wintoni* on the basis of multivariate analysis of external and cranial measurements (Rautenbach & Nel 1978, Watson 1990a, Kearney & Taylor 1997). However, on the basis of post-palatal measurements and morphometric analyses of cranial characters including palatal measurements by Hill (1974a), the specimens assigned to *L. wintoni* by Kearney & Taylor (1997) have now been re-identified as *L. botswanae* (Kearney & Seamark 2005). Specimens from Algeria Forest in the Western Cape (South Africa) originally described by Rautenbach & Nel (1978) as *L. wintoni* were subsequently re-identified as *L. namibensis* in Skinner & Smithers (1990). However, new specimens from Algeria have been referred to as *L. wintoni* (based on Rautenbach & Nel 1978) by Jacobs *et al.* (2005). On the basis of morphometric analyses of cranial characters, including palatal measurements, the distinction between *L. wintoni* and *L. namibensis* could not be confirmed by Kearney & Seamark (2005); therefore, pending clarification of the status of *namibensis*, information from Jacobs *et al.* (2005) is mentioned in the profile for *L. namibensis*. Chromosome number (South Africa): 2n = 34; aFN = 50 (as in *L. botswanae* and *L. namibensis*) (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, of medium length for a vespertilionid (21–24 mm) and of medium relative length (53–60% of FA, n = 12); GLS 15.6–16.3 mm. A poorly known species. Sexes similar. Mid-dorsal hairs ca. 8 mm. Dorsal pelage yellowish-brown to reddish-brown; hairs distinctly bicoloured, basal 6 mm dark brown, terminal 2 mm yellowish-brown or reddish-brown. Ventral pelage with chin yellowish-orange, reddish-brown or pale brown, throat paler, pelvic region cream or white. Hairs (except in pelvic region) blackish-brown with yellowish-orange, reddish-brown, cream or white tips. Hairs in pelvic region pure white. Head fairly flat; naked skin on muzzle and around eyes is dark brown. Buccal pads observed in one ♂. Ears dark brown, roughly triangular but very elongated; tip rounded; inner margins almost meeting on forehead but not joined. Ears may be held erect above the head or (when resting) held horizontally at right-angles to head. Tragus as in Figure 129e. Wings dark brown or blackish-brown; presence or absence of hind-border is not known. Interfemoral membrane paler and more translucent.

Skull (as in all *Laephotis* spp.) with braincase slightly flattened; rostrum rather narrow; zygomatic arches slender; no sagittal crest; lambdoid crest weakly developed. Skull on average medium-long and wide for the genus (GLS: 15.6–16.3 mm; GWS: 8.8–9.5 mm). Palatal length: 8.1 (7.9–8.5) mm, n = 15.

Geographic Variation None recorded.

Similar Species Not easily distinguished from other *Laephotis*:

Laephotis angolensis. FA shorter (32–36 mm). Ears shorter (15–18 mm) and narrower. Skull shorter and broader (GLS: 13.7–13.8 mm; GWS: 6.7, 8.1 mm; C–M³: 4.3 mm).

L. botswanae. Forearm on average shorter (36.3 [30–39] mm). Skull usually smaller (GLS: 14.6 [14.1–15.5] mm; C–M³: 4.7 [4.5–4.9] mm).

L. namibensis. Skull usually longer (GLS: 16.1–17.0 mm). Dorsal pelage and wings sometimes creamy-brown (see Geographic Variation).

Distribution Endemic to Africa. Distribution disjunct. There are scattered records in the Afromontane–Afroalpine and Somalia–Masai BZs of Ethiopia and East Africa, and records much further south in the Afromontane–Afroalpine and Highveld BZs of South Africa. Recorded from Ethiopia (Koka, Shoa Province), Kenya (Kitui, Namanga, Nyeri, Nanyuki), Tanzania (West Usambara Mts and near Iringa), South Africa (Free State) and E Lesotho (Setzer 1971, Hill 1974a, Kock & Howell 1988, Watson 1990a, Kearney & Taylor 1997, Stanley & Kock 2004).

Habitat In Ethiopia, found at 1700 m, near a large Rift Valley reservoir on the Awash R. surrounded by *Acacia* woodland that has been extensively degraded to provide open farmland (Largen *et al.* 1974). In East Africa, recorded from highland and mountainous areas with mosaics of evergreen bushland, secondary *Acacia* wooded grasslands and farmlands, and forests on the mountains: caught in forests, near forests and in woodlands. In the Free State Province of South Africa, recorded amongst large exotic trees in a drainage line flanked by sandstone cliffs (Watson 1990a). In Lesotho, recorded from the vicinity of a dam surrounded by a vlei overgrown with medium-height (600 mm) vegetation in Sehlabathebe N. P. (Lynch & Watson 1990). In this N. P., there is no significant cover of tall grass,

*Laephotis wintoni*

forbs or woody vegetation; the climate is harsh; the topographical relief is fairly uniform, and the altitude is 2300–2650 m.

Abundance Rare, but numbers in museum collections are increasing.

Remarks Roosts not known, but the association of this bat with cliffs (in South Africa) indicates that it might roost in cracks and crevices of cliff-faces. In South Africa, active later than *Cistugo lesueuri* (Lynch & Watson 1990). Specimens have been caught while foraging for insects from early to mid-evening (18:30–21:40h). In Lesotho, one of three ♀♀ was pregnant (with one embryo) in Nov (Lynch & Watson 1990).

Conservation IUCN Category: Least Concern.

GENUS *Mimetillus* Moloney's Mimic Bat

Mimetillus Thomas, 1904. Abstr. Proc. Zool. Soc. Lond. 1904 (10): 12. Type species: *Vesperugo (Vesperus) moloneyi* Thomas, 1891.

*Mimetillus moloneyi*.

Pending revision, considered here to be a monotypic genus endemic to tropical Africa including Bioko I. (but see Cotterill [2001d] and Monadjem *et al.* [2010]). Diagnostic combination of characters: four upper and five lower cheekteeth and two upper incisors on each side; head conspicuously flattened; ears relatively short and not joined at base; outer margin of ear not reaching mouth; phalanges of third, fourth and fifth fingers very short (third finger shorter than HB); no body pattern; wings not reticulated. Dental formula: $2^{113}/_{3123} = 32$. Selected characters of *Mimetillus moloneyi* are illustrated in Figure 130. Placed in tribe Vespertilionini (Simmons 2005).

The only species is *Mimetillus moloneyi*.

Meredith Happold

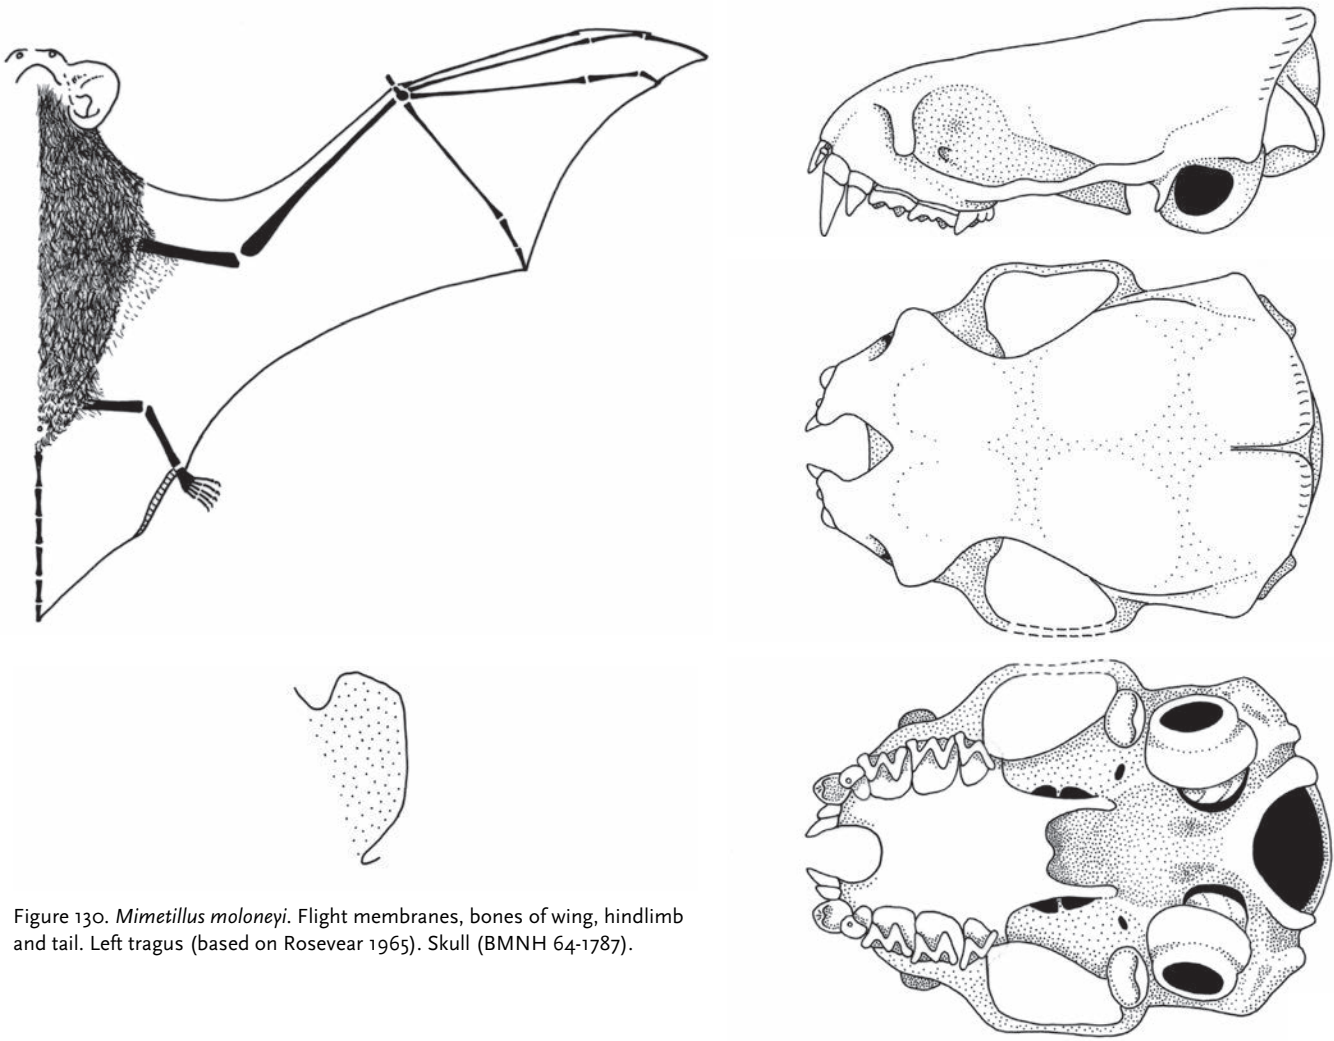

Figure 130. *Mimetillus moloneyi*. Flight membranes, bones of wing, hindlimb and tail. Left tragus (based on Rosevear 1965). Skull (BMNH 64-1787).

***Mimetillus moloneyi* MOLONEY'S MIMIC BAT (MOLONEY'S FLAT-HEADED BAT)**

Fr. Mimétille de Moloney; Ger. Moloneys Schmalflügel-Fledermaus (Moloneys Flachkopf-Fledermaus)

Mimetillus moloneyi (Thomas, 1891). Ann. Mag. Nat. Hist., ser. 6, 7: 528. Lagos, Nigeria.

Taxonomy Originally *Vesperugo* (*Vesperus*) *moloneyi*. Synonyms: *berneri*, *thomasi*. Subspecies: two recognized by Hayman & Hill (1971) and Simmons (2005), three by Koopman (1994) and, pending revision, three are tentatively recognized here. Cotterill (2001d) considers *thomasi* to be a distinct savanna species, which is larger than the forest-dwelling nominate subspecies, but additional locality records and morphometric data (see Geographic Variation) indicate a more complex pattern and, pending further evidence, only one species of *Mimetillus* is recognized here. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (9–14 mm); tragus mushroom-shaped; wings extremely short and narrow; head conspicuously flattened and with broad muzzle. No apparent sexual dimorphism.

Pelage velvety; mid-dorsal hairs 2–3 mm. Dorsal and ventral pelage dark chocolate brown to almost black; hairs unicoloured. Head uniquely flattened for an African vespertilionid; muzzle with very large glands in sexually active animals. Ears blackish, naked, short, pointed. Tragus very short, mushroom-shaped. Wings dark brown to black with finger-wing translucent; extremely narrow, short and pointed (at first glance of juvenile appearance). Phalanges of third, fourth and fifth fingers relatively very short, third finger shorter than HB. Legs very short and stout. Tail 44–49% of HB. Penis remarkably long (12.8 mm; Gallagher & Harrison 1977), possibly without baculum (Hill & Harrison 1987).

Skull (Figure 130) with braincase greatly flattened (viewed laterally, profile of rostrum and braincase is a straight line). Rostrum shortened, very broad, with well-developed supraorbital tubercles (ante-orbital inflation of the maxillary bones). Postorbital constriction very pronounced. Skull (viewed dorsally) almost circular in outline. Sagittal crest negligible; lambdoid crest fairly well developed. Outer

upper incisors comparatively long and lateral to the inner upper incisor. Upper canine without secondary cusp. Upper premolar exceeding height of molars.

Geographic Variation Koopman (1994) recognizes three subspecies. Simmons (2005) recognizes only two, *moloneyi* and *thomasi*, and considers a third form, *berneri*, to be a synonym of *thomasi*. The status of *thomasi* and *berneri*, and their affinities, are controversial and therefore, solely for convenience, they are both listed here as subspecies:

M. m. moloneyi. SE Guinea and Sierra Leone to W Ethiopia, Kenya and NE Tanzania, and southwards to NW Angola (Cabinda enclave) and W DR Congo. Forest, forest–savanna mosaic and savanna habitats. FA: 28.9 (27–31) mm, $n = 16$; GLS: 13.8 (13.0–15.1) mm, $n = 64$; C–M³: 4.8 (4.1–5.3) mm, $n = 65$. Considered by Cotterill (2001d) to be smaller and darker than the other forms, but there is considerable overlap in measurements, and bats from humid forest habitats are often darker than those from drier habitats and therefore colour can be unreliable as an indicator of taxonomic status.

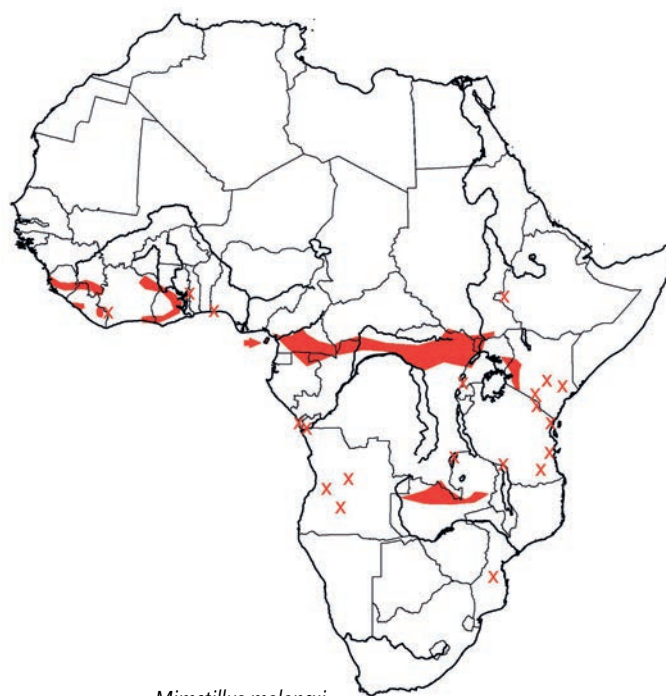

M. m. thomasi. SE DR Congo, S Tanzania, Zambia and Mozambique. Mostly savanna habitats. FA: no information; GLS: 14.4 (14.0–14.9) mm, $n = 11$; C–M³: 5.1 (4.8–5.4) mm, $n = 13$ (Cotterill 2001d). Considered by Cotterill (2001d) to be larger and paler than *M. m. moloneyi*, and to be a distinct species.

M. m. berneri. WC Angola. Savanna habitats. Body measurements similar to those of *M. m. moloneyi*, but craniodentally on average larger. FA: 30.6 (29–31) mm, $n = 5$; GLS: 14.2 (13.6–14.7) mm, $n = 5$; C–M³ (alv.): 5.0 (4.6–5.4) mm, $n = 4$. Considered a subspecies endemic to the Angolan Plateau by Crawford-Cabral (1986). Considered to be a synonym of *thomasi* by Cotterill (2001d) and Simmons (2005). The type locality, Cubango Mission (Vila da Ponte; Monard 1933), was incorrectly given as Chitau by Cotterill (2001d).

Similar Species None. Distinct from any other African bat and one of the most unusual vespertilionids.

Distribution Endemic to Africa. Recorded mainly from the northern fringe of the Rainforest BZ (Western, West Central and East Central Regions), the Rainforest–Savanna Mosaics, the Somalia–Masai Bushland, Coastal Forest Mosaic and Zambezan Woodland BZs, with marginal extensions into the Sudan Savanna BZ in Ethiopia, and the Guinea Savanna BZ in N Côte d'Ivoire and S Sudan. Recorded from Guinea (Ziéla, Mt Nimba; MNHN) and Sierra Leone to W Ethiopia and S Kenya, and southwards (avoiding most of the central Congo Basin), to Angola, Zambia and Mozambique. Also Bioko I. (but not mainland Equatorial Guinea). Not yet recorded from Dahomey Gap in West Africa (a single record from Odomi Jongu is situated in the partly forested Volta Highlands of Ghana) and the southern rainforest–savanna mosaic in DR Congo. For subspecific distributions, see Geographic Variation.

Habitat *Mimetillus m. moloneyi* was generally assumed to prefer rainforest, but most of the records within this zone are in a very narrow band along the northern border of the Rainforest BZ, and this bat is conspicuously absent from most of the interior of the (formerly) closed rainforest zone of the Western Region, and from

Mimetillus moloneyi

most of the central Congo Basin. Furthermore, it extends well outside the Rainforest BZ. Recorded in lowland rainforest (mostly drier types), coastal forest, montane forests, mangroves, forest–savanna mosaics, *Acacia–Commiphora* bushland and thicket, and *Isoberlinia* woodland. The distribution and habitats suggest that this bat prefers the edge of the rainforest from which it penetrates into the adjacent forest–savanna mosaic and woodlands. In East Africa, found up to 2300 m (Kingdon 1974).

The southern subspecies seem to prefer drier vegetation types: *M. m. thomasi* has been recorded from mopane and miombo woodlands, *Cryptosepalum* dry forest, and the Coastal Forest Mosaic at Rufiji River, S Tanzania. The subspecies *M. m. berneri* is known from miombo woodland and montane forest–grassland mosaic on the Angolan Plateau.

Abundance Probably not uncommon but, because it flies high and is not easily captured at its roosts, it is comparatively rarely encountered.

Adaptations Aspect ratio low; wing-loading exceptionally high (higher than in any other vespertilionid for which data are available except *Nyctalus leisleri*); wing-tip unusually pointed; wing morphology the most extreme of all bats examined and the characteristics of its flight are hard to predict – presumably fast with poor agility and poor manoeuvrability (Norberg & Rayner 1987). Flies fast, either straight or in wide shallow arcs, without sudden turns; wing-beat unusually rapid (whirring of wings can be heard as bat flies overhead); cannot take off from ground and needs to dive from its roost to gain sufficient speed for flight (Lang & Chapin 1917b, Brosset 1966, Kingdon 1974). However, an individual hunting under the roof of an open and spacious dining hall was observed making narrow and abrupt turns as well as flying in straight or shallowly curved lines (N. Ebigo & K. Soer pers. comm.). This individual clung to one of the ceiling beams and repeatedly flew off in direct lines with narrow and

abrupt curves at the turning points before returning to the starting point. Climbs well; scuttles over ground in fast, jerky manner with body held well clear of substrate; when resting, the body is flattened and the ears folded down (Kingdon 1974). By day, roosts under bark of dead trees in forest clearings, at 8–12 m above ground (Brosset 1966), also roosts in native houses and roofs (BMNH, ROM), and one was found in a hollow baobab tree *Adansonia digitata* (Cotterill 2001d). The flattened skull and body, and the very short pelage, are probably adaptations facilitating roosting under bark, in narrow cracks and fissures. Compared to other vespertilionids, the mammae are positioned far back along the abdomen (Ansell 1967); possibly their position is related to the way ♀♀ carry their young in flight or in the roost.

Foraging and Food Usually forages at medium height in clearings or above vegetation; foraging strategy likely to be variable. In Comoé N. P., Côte d'Ivoire, four individuals were captured at heights of 9.3–11.1 m, in mist-nets set 0–25 m above ground. In Taï N. P., two individuals were caught at heights of 1.1 and 1.9 m in mist-nets set over a small forest stream, but possibly these bats, as well as others caught over ponds and streams elsewhere, were descending to drink (J. Fahr unpubl). Foraging commences at dusk. Evidently the early hunt can be very successful: bats were observed to return to their day-roost after short foraging bouts of 10–15 min; at Double R. (Liberia), one individual with a full stomach was captured at 19:15h (Brosset 1966; Verschuren 1976 as *Eptesicus capensis*). Diet includes small winged termites (Lang & Chapin 1917b), and presumably other small to medium-sized flying insects. Kingdon (1974) caught a bat that had the head of a large-jawed ant attached to the corner of the mouth.

Social and Reproductive Behaviour Two colonies in Gabon, checked time and again, comprised 9–12 individuals (Brosset 1966).

Reproduction and Population Structure Litter-size: one ($n = 4$). Reproductive chronology uncertain; the limited data are consistent with seasonal bimodal polyoestrus with postpartum oestrus and births six months apart, but the gestation period is not known and the possibility of asynchronous breeding and/or more than two births per year cannot be ruled out. At 07° 54' N (near Lalehun, Sierra Leone), two pregnant ♀♀ (crown–rump length of embryos 7 and 8 mm) and one ♂ with large testes, were found in late Jan, and one of the ♀♀ was also lactating (USNM), indicating polyoestrus with postpartum oestrus at least in that ♀. Observations of a pregnant ♀ at end of Mar (05° 50' N, Taï N. P., Côte d'Ivoire), a lactating ♀ in mid-May (08° 45' N, Comoé N. P., Côte d'Ivoire) and a pregnant ♀ in mid-Oct (06° 27' N, Lagos, Nigeria) are also consistent with polyoestrus in West Africa (BMNH, FMNH, USNM, J. Fahr unpubl.). At 01° 08' N (Bélinga, Gabon) one ♀ was pregnant close to term in late Feb (Brosset 1966). In Uganda (locality not

given), 4 of 4 ♀♀ were pregnant (and a ♂ had large testes) in Jan, 1 of 1 was lactating in Mar, 2 of 2 were pregnant and one of these was also lactating (and a ♂ had large testes) in Jun, suggesting seasonal bimodal polyoestrus with births in Feb or Mar and again in Aug (Kingdon 1974). Furthermore, nearby at 01° 35' N (Wei-Wei R., W Kenya), a ♀ with an embryo 22 mm in length was found in late Jul (FMNH).

Predators, Parasites and Diseases Predators include the Bat Hawk *Macheiramphus alcinus* (Lang & Chapin 1917b). Kingdon (1974) reasoned that larger hornbills (Bucerotidae) might be important predators as they spend much time probing loose bark. Ectoparasites include mites *Carios vespertilionis* (Acari: Argasidae), *Acanthophthirus mimetilli* (Acari: Myobiidae), *Pteracarus mimetillius* (Acari: Myobiidae) and *Notoedres mimetilli* (Acari: Sarcoptidae) (Anciaux de Faveaux 1984, Uchikawa 1989).

Conservation IUCN Category: Least Concern.

If this species prefers forest-edge habitats (see Habitat), it is likely to be favoured by moderate degradation of the rainforest and the creation of clearings within what was formerly closed forest. In this case, its area of occupancy is likely to increase.

GENUS *Nyctalus*

Noctules

Nyctalus Bowdich, 1825. Excursions in Madeira and Porto Santo, 36, footnote. Type species: *Nyctalus verrucosus* Bowditch, 1825 (= *Vespertilio leisleri* Kuhl, 1817).

This widespread Palearctic genus has six species, of which at least two occur in NW Africa. Diagnostic combination of characters (African species): five upper and five lower cheekteeth and two upper incisors on each side; FA: 41–64 mm, wings particularly narrow (fifth finger shortened [ca. equal third and fourth metacarpals]); ventral pelage extending onto arm-wing and marginally onto hand-wing. Wings dark, leathery and opaque. Muzzle short and somewhat flattened. Ears relatively short and rounded; tragus short and kidney-shaped. Dorsal profile of skull is a smooth convex curve from front to back; rostrum broad and robust; rostral emargination unusually large (extending back half-way to the interorbital constriction) (Figure 131). Dental formula: $\frac{2123}{3123} = 34$. Second upper incisor deeply concave, with a large anterior and a small posterior secondary cusp. Anterior upper premolar extremely small and often not visible from outside. The first and second upper molars have a small but rather distinct hypocone. Selected characters of *Nyctalus* are illustrated in Figure 131.

Not surprisingly, the two species found in Africa are the most southern of the European species, one of them extending its geographic

Nyctalus leisleri.

Figure 131. African *Nyctalus*. Ventral view of flight membranes showing areas covered by pelage, and bones of wing, hindlimb and tail (e.g. *N. lasiopterus*). Left ear and tragus of *N. lasiopterus* (based on Ibáñez *et al.* 2004). Postcalcaneal lobe with T-shaped cartilage (e.g. *N. leisleri*). Skull (e.g. *N. lasiopterus*; ZFMK 46.297, partly based on Ibáñez *et al.* 2004).

range also to Madeira and Canary Is. Noctules are migratory and, until recently, their occurrence in North Africa was suspected to reflect occasional crossings of the Mediterranean Sea. However, the finding of breeding colonies clearly indicates that *N. leisleri* is fully part of the African fauna. Possibly, *N. noctula* also occurs in North Africa, but this needs confirmation. There is only one reliable record in Algeria (Loche 1858) – two specimens (one ♂ and one ♀) collected in a hollow tree in Cheliff plain, which were lost with the rest of Loche's collection. According to Palmeirim (1982), possibly they belonged to *N. lasiopterus*, this species being considered as conspecific by earlier zoologists. There are some doubts as to the place of origin of the specimens of *N. noctula* in the BMNH (Palmeirim 1982) and in the RMNH (Jentink 1888): one was mentioned by Dobson (1878) as having been bought in Algiers, and Kowalski & Rzebik-Kowalska (1991) suggest that all were bought from professional dealers in zoological specimens. Hayman & Hill (1971) also expressed doubts as to the true provenance of Peters's specimens of *N. macuanus*, reported from Mozambique and later included in the synonymy of *N. noctula*.

Because its occurrence in Africa is uncertain, there is no profile for *N. noctula* here.

Noctules are tree-dwelling species. Although they are found in buildings in some parts of their range, they mainly roost in hollow trees in deciduous forests and parks, so they are restricted to the Mediterranean habitats of the Maghreb and Cyrenaica. Noctules in flight resemble pipistrelles and both leave their roosts before or just after sunset.

The two species known to occur in North Africa, and *N. noctula* which might occur there, can be identified by the following combination of characters:

N. lasiopterus. FA: 59–69 mm throughout geographic range.

N. leisleri. FA: 35–46 mm throughout geographic range; dorsal hairs dark brown at base becoming golden-brown towards tip.

N. noctula. FA: 45–57 mm; dorsal pelage unicoloured.

Stéphane Aulagnier

Nyctalus lasiopterus GIANT NOCTULE

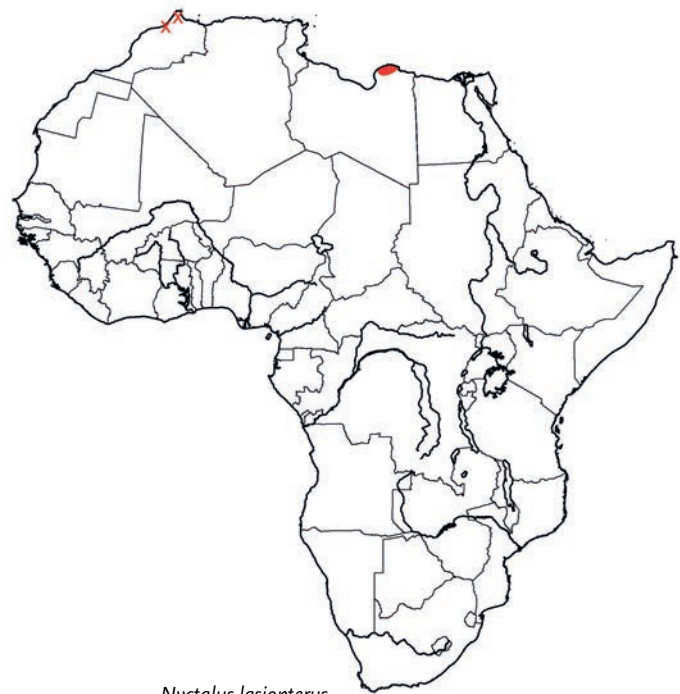

Fr. Grand noctule; Ger. Riesenabendsegler

Nyctalus lasiopterus (Schreber, 1780). In: Zimmermann, Geogr. Gesch. Mensch. Vierf. Thiere 2:412. ? Pisa (uncertain), northern Italy.

Taxonomy Originally *Vespertilio lasiopterus*. Synonyms: *ferrugineus*, *maxima*, *sicula*. Subspecies: none. Chromosome number (Europe): $2n = 42$; $aFN = 50$ (Volleth 1992).

Description Medium-sized microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and five lower cheekteeth and two upper incisors on each side; ears separated, of medium length for a vespertilionid (19–23 mm) but relatively short (33–35% of FA); fifth metacarpal notably shorter than third and fourth (cf. *Pipistrellus*); FA: 59–64 mm. Sexes similar. Pelage dense, glossy in spring, summer and autumn; ventral pelage extending on to wings and interfemoral membrane as in Figure 131; mid-dorsal pelage 10–13 mm. Dorsal pelage rufous-brown; hairs unicoloured. Ventral pelage paler. Muzzle dark brown. Ears dark brown, widely separated, relatively short (33.9 [33–35]% of FA, $n = 4$ from southern Spain), broad, roughly triangular but tip very rounded; outer margin with four folds. Tragus kidney-shaped. Wings dark brown, long and narrow, fifth metacarpal notably shorter than third and fourth. Wing-membrane attaching to side of hindfoot (metatarsus). Interfemoral membrane dark brown with ventral pelage extending over proximal quarter. Calcar reaching half-way towards tip of tail. Postcalcareal lobe wide with visible T-shaped piece of cartilage. Hindfoot less than half length of tibia.

Skull (Figure 131) large and robust (cf. *N. leisleri*); rostrum broad; viewed laterally, the dorsal profile is a smooth convex curve from front to base of helmet. Sagittal crest weakly developed; lambdoid crest moderately developed forming a low occipital helmet. Dentition massive. Anterior upper premolar small (ca. level with cingulum of posterior premolar), fully displaced lingually; canine and posterior premolar in contact (therefore anterior premolar not visible from the outside).

Nyctalus lasiopterus

Geographic Variation None recorded in Africa. African specimens seem to have shorter forearms than specimens from Eastern Europe, but sample sizes are small (Ibáñez *et al.* 2004).

Similar Species Only two other vespertilionids occurring (or perhaps occurring) in North Africa have five upper and five lower cheekteeth and two upper incisors on each side; ears not joined at base; FA: >40 mm:

Nyctalus leisleri. Much smaller (FA: 35–46 mm throughout geographic range).

N. noctula Smaller (FA: 45–57 mm). Occurrence in Africa uncertain.

Distribution In Africa, recorded in the Mediterranean Coastal BZ of North Africa, from two widely separated regions: in the Rabat area and Rif mountains of Morocco (Laurent 1937, Palmeirim 1982, Ibáñez 1988), and in the mountains of Cyrenaica, Libya (Qumsiyeh & Schlitter 1982, Spitzenberger 1982). These African populations are considered to be sedentary. Possibly also recorded from Algeria (see genus *Noctula*). Extralimittally: this Palearctic species occurs from Mediterranean Europe to Iran and Kazakhstan.

Habitat Associated with well-preserved Mediterranean forests of cork oak *Quercus suber* and semi-deciduous oak *Q. canariensis* in Morocco, and with forest of cypress *Cupressus sempervirens* and juniper *Juniperus excelsior* in Libya. African specimens were captured at altitudes 0–800 m. In southern Iberia, also found in city-parks with old-grown trees.

Abundance Rare in Africa. Only two specimens known from Morocco and nine from Libya.

Adaptations Aspect ratio medium; wing-loading high (Ibáñez *et al.* 2001). Can take off from ground (with difficulty); when leaving day-roost, dives for up to 3 m to gain sufficient speed for flight. Sometimes scuttles and climbs around inside its roosts. Roosts by day in holes in mature trees, and under old, dry leaves of tall palms *Washingtonia filirifera*; also roosts in bat-boxes (Dondini & Vergari 2000, Ibáñez *et al.* 2004). One individual from Cyrenaica, Libya, was captured in a little cave (Spitzenberger 1982). In southern Iberia, active all year around except from Dec to Feb (Ibáñez *et al.* 2001); probably hibernates in Dec–Feb but this has not been confirmed.

Foraging and Food Based on wing morphology, echolocation and visual observations, forages by fast-hawking in open spaces (e.g. above canopies and over marshes) more than 50 m above ground (Ibáñez *et al.* 2004). The occasional presence, in faeces, of non-flying prey (e.g. Opiliones), and other prey which is inactive at night, suggests that this bat also gleans or captures prey inside its day-roosts (Dondini & Vergari 2000). Moves daily more than 25 km from roosts to foraging areas (Ibáñez *et al.* 2004). Diet (in Europe) includes a wide range of invertebrates and also small birds. Analysis of more than 14,000 faecal pellets indicated that birds comprised up to 50% of the diet (both in frequency and volume) during the nocturnal migration of small passerines in autumn and spring (Ibáñez *et al.* 2001).

Echolocation Search-phase call-shape >50 m above ground (Iberia): steep/shallow FM; fundamental harmonic only (Figure 132a). Start-frequency 25.1 kHz; end-frequency 17.6 kHz; bandwidth 7.5 kHz; peak-frequency 18.8 kHz; call-duration 12.3 ms; inter-call interval 319.7 ms (Ibáñez *et al.* 2001). Uses consecutive calls of alternate frequency as does *Nyctalus noctula* (not found in Africa) although more rarely and only during flights at low altitude (<20 m) (Ibáñez *et al.* 2004). At low altitude, call-shape is steep FM/QCF and the second harmonic is present (Figure 132b).

Figure 132. Sonograms of search-phase echolocation calls of *Nyctalus lasiopterus* from Seville, Spain. (a) In flight at high altitude (> 50 m): successive calls have same frequency; only the fundamental harmonic is present; bandwidth comparatively narrow; inter-call interval comparatively long. (b) In flight at low altitude (< 20 m) a few minutes after leaving roost: successive calls differ in frequency; second harmonic present; bandwidth wider; inter-call interval shorter.

Social and Reproductive Behaviour Very little information. Establishes maternity colonies of up to 80 ♀♀ (no ♂♂). Vocalizations in the maternity colonies are frequent even during the day. These social calls have high intensities; each sequence comprises 25 calls with tonal structure, which are slightly modulated with end-frequencies between 9 and 15 kHz; therefore they are audible to humans and have a characteristic metallic tone (Ibáñez *et al.* 2004). As yet, there is no information about the roosting behaviour of ♂♂.

Reproduction and Population Structure Litter-size (Europe): one or two (frequencies not known). Extralimittally, in southern Iberia, the reproductive chronology is restricted seasonal monoestry with ♂♂ showing well-developed scrotal testes from early Aug to Oct (mid-summer to mid-autumn), and ♀♀ giving birth at end of May or early Jun (late spring) and lactating until early Aug (Ibáñez *et al.* 2004). A neonate born in captivity weighed 9.9 g and had forearm 26.5 mm (Topál 1976). Young are volant by ca. 40 days (Aleksseva 1988).

Predators, Parasites and Diseases Several cases of predation by the Barn Owl *Tyto alba* are known in Europe. A predation by Beech Marten *Martes foina* is reported from Crimea (Ibáñez *et al.* 2004).

Conservation IUCN Category: Near Threatened (assessed mainly from extralimittal data).

Ongoing reduction of Mediterranean forests in North Africa as result of human activities and desertification is likely to severely reduce population numbers. Almost qualifies for Vulnerable.

***Nyctalus leisleri* LEISLER'S NOCTULE (LEISLER'S BAT)**

Fr. Noctule de Leisler; Ger. Kleinabendsegler

Nyctalus leisleri (Kuhl, 1817). Die Deutschen Fledermäuse. Hanau, pp. 14, 46. Hanau, Hessen, Germany.

Taxonomy Originally *Vespertilio leisleri*. Synonyms: four; none in Africa. Subspecies: two; only the nominate occurs in Africa. Chromosome number (Poland, Czechoslovakia): 2n = 46; aFN = 50 (Fedyk & Fedyk 1970, Zima 1978).

Description Small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and five lower cheekteeth and two upper incisors on each side; ears separated, short for a vespertilionid (13–16 mm) and also relatively short; fifth metacarpal notably shorter than third and fourth (cf. *Pipistrellus*); FA: 41–44 mm. Sexes similar. Pelage soft, sleek, dense; mid-dorsal hairs 7–9 mm; ventral pelage extending on to wings and interfemoral membrane. Dorsal pelage golden-brown; hairs dark brown at base becoming golden-brown towards tip. Ventral pelage slightly paler (yellowish); hairs blackish-brown with brown tip. Muzzle dark brown. Ears dark brown, widely separated, relatively short, subtriangular but with very rounded tip; outer margin with 4–5 folds. Tragus kidney-shaped, short, blunt. Wings dark brown, long and narrow; fifth metacarpal notably shorter than third and fourth metacarpals (ca. 80–85% of third metacarpal, n = 3). Wing-membranes attaching to ankle. Interfemoral membrane dark brown. Calcar reaching half-way to tip of tail. Postcalcareal lobe wide with visible T-shaped piece of cartilage (Figure 131).

Skull small (cf. *N. lasiopterus*); rostrum broad; viewed laterally, the dorsal profile is a smooth convex curve from front to back. No sagittal crest; lambdoid crest weakly developed; no occipital helmet. Dentition moderately weak. Incisors relatively small. Anterior upper premolar visible from the outside. Height of mandibular ramus: 2.9–3.6 mm.

Geographic Variation None recorded in Africa.

Similar Species Only two other vespertilionids occurring (or perhaps occurring) in North Africa have five upper and five lower cheekteeth and two upper incisors on each side; ears not joined at base; FA: >40 mm:

Nyctalus lasiopterus. Much larger (FA: 59–69 mm throughout geographic range). Height of mandibular ramus >5.0 mm.

N. noctula. Larger (FA: 45–57 mm). Height of mandibular ramus 4.3–4.8 mm. Pelage unicoloured. Occurrence in Africa uncertain.

*Nyctalus leisleri*

Distribution In Africa, recorded in the Mediterranean Coastal and Afromontane-Afroalpine BZs from the mountains of Morocco (Rif, High Atlas), Algeria (Tell Atlas) and Libya (Cyrenaica) (Hanák & Gaisler 1983, Ibáñez 1988, Kowalski & Rzebik-Kowalska 1991, Benda *et al.* 2004d). Presumably also occurs in N Tunisia although not yet recorded there. Extraliminally: this Palearctic species ranges from western Europe (and Madeira I.) through Urals and Caucasus to the W Himalayas.

Habitat All of the North African specimens were mist-netted in, or near, forests at 400–900 m; mainly oak forests (*Quercus suber*, *Q. ilex*, *Q. faginea*, *Q. canariensis*), and also juniper-cypress forest (*Juniperus excelsa*, *Cupressus sempervirens*), where they often foraged over streams (Hanák & Gaisler 1983, Gaisler & Kowalski 1986, Ibáñez 1988, Benda *et al.* 2004d).

Abundance Uncertain. As for nearly all the tree-dwelling species that require specific surveys, most of the records in North Africa are recent. Particularly abundant in mist-net captures in Djurdjura (NE Algeria) (Gaisler & Kowalski 1986). Population size limited by the reduced distribution of suitable habitats.

Adaptations Aspect ratio medium; wing-loading very high (Norberg & Rayner 1987). Flight fast; manoeuvrability predicted to be poor. In summer, roosts by day mainly in tree-holes, under bark (including for breeding colonies) and occasionally in buildings. In winter, hibernates in hollow trees and sometimes in rock-crevices (Schober & Grimmberger 1987). Hibernation period in Africa shorter than in Europe – in Algeria, ♂♂ were active in mid-Oct (Gaisler & Kowalski 1986). Migrates: longest recorded movement 1567 km, from Germany to Spain (Ohlendorf *et al.* 2000).

Foraging and Food Forages by fast-hawking over open areas and above canopies; foraging flights fast, straight, often with dives. Foraging mainly occurs during two periods, the first after dusk and the second ending ca. 30 min before dawn. Occasionally flies during the day. Foraging areas average 7.4 km², but are up to 18.4 km² in southern Britain (Waters *et al.* 1999). Diet: no information for Africa. In Ireland and England, Diptera (Nematocera and Cyclorrhapha) are the predominant prey, but Coleoptera, Trichoptera and Lepidoptera are also important (Sullivan *et al.* 1993, Waters *et al.* 1995, 1999, Vaughan 1997). In Germany and Switzerland, Lepidoptera, Nematocera and Neuroptera may, at least locally, be important items of food (Beck 1995, Shiel *et al.* 1998).

Echolocation Search-phase calls (above level of treetops) are of two types. (a) Call-shape QCF; start-frequency 26–28 kHz; end-frequency 22–24 kHz; peak-frequency 22–24 kHz; call-duration 15–25 ms. (b) Call-shape shallow FM; start-frequency 26–30 kHz; end-frequency 25–26 kHz; peak-frequency 25–26 kHz; call-duration 7–15 ms; intercall-interval 220–550 ms (Waters *et al.* 1995, Tupinier 1996).

Social and Reproductive Behaviour Mating takes place in late summer. Males are very territorial at this time; each ♂ is assumed to attract ♀♀ by means of an ‘advertisement song’ (von Helversen & von Helversen 1994) and occupies a mating-roost with a harem of up to nine ♀♀. During winter, ♂♂ and ♀♀ hibernate together in large groups. In summer, ♀♀ form maternity colonies of 10–50 individuals (exceptionally several hundred in attics in Ireland; Shiel &

Fairley 1999); adult ♂♂ and immature bats roost elsewhere. In Poland, maternity colonies in trees comprised 20.7 (7–38) individuals; roost-fidelity was low (Ruczynski & Ruczynska 1999). Maternity roosts are vacated by late Aug to early Sep.

Reproduction and Population Structure Litter-size (Western Europe): usually two. In Europe, the reproductive chronology is restricted seasonal monoestry with mating in late summer (late Aug–Sep); births in mid-summer (Jun–Jul); young are volant one month later (Pottier 1993, Shiel & Fairley 1999). In Morocco, births occur in May and by mid-Jul juveniles are almost the same size as adults (Ibáñez 1988). Maximum life-span: nine years (Schober & Grimmberger 1987).

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern (assessed mainly from extralimital data).

Loss of habitat because of logging and overgrazing is the main threat in North Africa.

GENUS *Nycticeinops*

Schlieffen's Twilight Bat

Nycticeinops Hill & Harrison, 1987. Bull. Br. Mus. Nat. Hist. 52: 254. Type species: *Nycticeius schlieffeni* Peters, 1859.

Nycticeinops schlieffeni.

A monotypic genus endemic to Africa south of the Sahara. Diagnostic combination of characters: four upper and five lower cheekteeth and one upper incisor on each side (as in *Otonycteris*, *Scotoecus* and *Scotophilus*); ears relatively short (cf. *Otonycteris*); penis short (cf. *Scotoecus*); FA: 28–35 mm (cf. 41–88 mm in *Scotophilus*); dental

formula: $^{1113}_{3123} = 30$. Selected characters of *Nycticeinops* are illustrated in Figure 133.

Based on bacular morphology, Hill & Harrison (1987) removed *schlieffeni* (the only African member of the genus *Nycticeus*) into a new genus, *Nycticeinops*. *Nycticeinops* is considered a subgenus of *Nycticeus* by Koopman (1994), but chromosomal evidence from one specimen from Somalia provides additional support for the generic status of *Nycticeinops* (Ruedas *et al.* 1990): the chromosome numbers for the Somali specimen are $2n = 34$, $aFN = 52$ compared with $2n = 46$, $aFN = 48$ for *Nycticeus humeralis*, a species from North America. This difference would represent one of the largest intra-generic differences in diploid number within the Vespertilionidae, which strongly indicates that *Nycticeinops* and *Nycticeus* are not congeneric. Mitochondrial ribosomal sequences provide further support for the generic distinction between *Nycticeus* and *Nycticeinops* (Hoofe & Van Den Bussche 2001). However, Rautenbach *et al.* (1993) found the karyotypes of 22 specimens of *N. schlieffeni* from southern Africa to be $2n = 42$, $aFN = 50$ (i.e. different from that of the specimen from Somalia). The difference between the karyotype of these southern African specimens and that of *Nycticeus humeralis* is not so marked and therefore Rautenbach *et al.* (1993) retained *schlieffeni* in *Nycticeus*. It is possible that the material from Somalia and that from South Africa represents two distinct species (G. N. Bronner pers. comm.). Alternatively, the identity of the Somali specimen

Figure 133. *Nycticeinops schlieffeni*. Flight membranes, and bones of wing, hindlimb and tail. Left ear and tragus. Details of tragus. Skull (MNHN CG 1997-2104).

might be erroneous. *Nycticeinops* is placed in the tribe Vespertilionini by Hooper & Van Den Bussche (2001) and in tribe Nycticeiini (with *Scotoecus* and *Scotophilus*) by Simmons (2005).

The only described species is *Nycticeinops schlieffeni*.

Meredith Happold

Nycticeinops schlieffeni SCHLIEFFEN'S TWILIGHT BAT (SCHLIEFFEN'S BAT)

Fr. Nycticinope de Schlieffen; Ger. Schlieffens Abendfledermaus

Nycticeinops schlieffeni (Peters, 1859). Monatsber. K. Preuss. Akad. Wiss. Berlin 1859: 223. Cairo, Egypt.

Taxonomy Originally *Nycticejus schlieffeni*. Synonyms: *adovanus*, *africanus*, *albiventer*, *australis*, *bedouin*, *cinnamomeus*, *fitzsimonsi*, *minimus*. Subspecies: uncertain (see Geographic Variation). Chromosome number (South Africa): $2n = 42$; $aFN = 50$ (Rautenbach *et al.* 1993). This differs markedly from the $2n = 34$; $aFN = 52$ karyotype reported for a specimen from Somalia (Ruedas *et al.* 1990) (see Genus *Nycticeinops*).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and only one upper incisor on each side; ears well separated, short for a vespertilionid (9–13 mm); FA: 28–35 mm; wings dark brown; penis 5.6–6.2 mm; anterior lower premolar ca. half height and half crown area of posterior premolar. Sexes similar in colour and size. Pelage dense, soft, slightly fluffy, with no sheen; mid-dorsal hairs 4–6 mm. There is considerable variation in colour. Dorsal pelage cinnamon, fawn or greyish-fawn; hairs unicoloured. Ventral pelage slightly to considerably paler, whitish or pure white. Head slightly flattened; muzzle short with prominent lateral glandular swellings. Ears dark brown; comparatively and relatively short for a vespertilionid (36.1 [31–42]% of FA); inner margin slightly convex, outer margin slightly concave; tip rounded. Tragus length 43.7 (40–50)% of E; shape as in Figure 133. Eyes very small. Wings and interfemoral membrane dark brown with blackish-brown venation. Free edge of interfemoral membrane with faint white border in some individuals. Penis comparatively short (5.6–6.2 mm, $n = 9$) (cf. *Scotoecus albobfuscus*, *S. hirundo*). Baculum with expanded bifid base and long fluted shaft with pointed tip (Hill & Harrison 1987).

Skull (Figure 133) somewhat flattened and fairly broad; dorsal profile (viewed laterally) rising at gentle slope from incisors to lambdoid crest; frontal area slightly concave. Zygomatic arches slender and weak but seldom lost during preparation of skulls (cf. *Scotoecus*). Sagittal crest absent or very low and only over posterior of braincase; lambdoid crest weakly developed; no occipital helmet. Upper incisor fairly long, unicuspid. Canines (upper and lower) robust; upper canine with anterior surface rounded and not grooved. Upper premolar sharply pointed, reaching to two-thirds to three-quarters height of canine. Posterior upper molar with three ridges (cf. *Scotophilus*). Lower incisors tricuspid. Anterior lower premolar ca. half height and half crown area of posterior lower premolar (cf. *Scotoecus*).

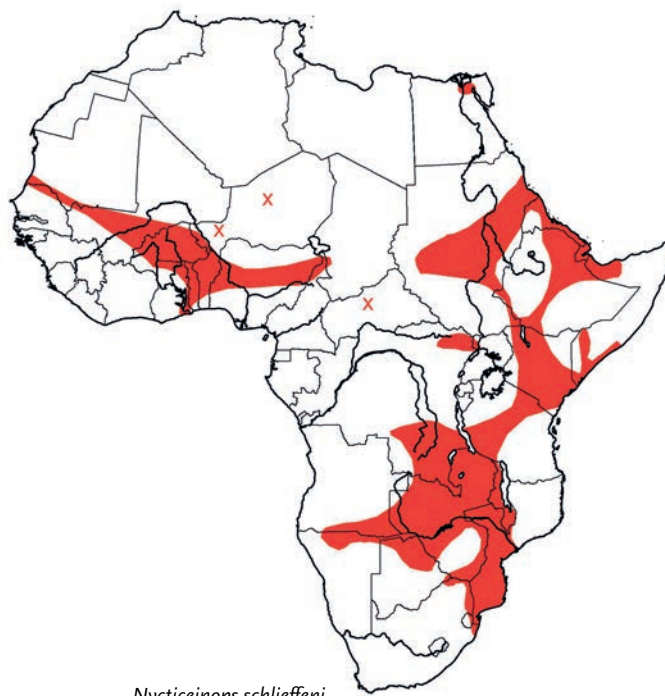

Geographic Variation Four subspecies (*albiventer*, *australis*, *fitzsimonsi* and *schlieffeni*) were recognized by Hayman & Hill (1971), but they are based largely on colour and are of dubious validity

(Rosevear 1965, Koopman 1994) and are not recognized by Simmons (2005). Specimens from Mozambique and KwaZulu–Natal, South Africa (the form *australis*) are darker than those from elsewhere.

Similar Species Only one other dark-winged vespertilionid in Africa has only one upper incisor on each side and FA <41 mm:

Scotoecus hirundo. Usually heavier (10.2 [8–15] g). FA sometimes longer (28–40 mm). Dorsal pelage chocolate brown, or medium to pale sepia brown; ventral pelage grey, beige, greyish-white or pale beige. Tragus less pointed (Figure 144b). Penis extremely long (14–16 mm). Upper canine with anterior surface flat and shallowly grooved. Anterior lower premolar at least two-thirds height of posterior premolar, usually only slightly shorter.

Distribution In Africa, recorded from the Sahara Arid BZ near the Nile R. in N Egypt, and in almost all biotic zones and mosaics south of the Sahara except the Rainforest, South-West Arid and Highveld BZs. Recorded disjunctly from Mauritania to Sudan, Eritrea, Djibouti and Somalia (with outlying localities near the Nile R. in N Egypt), and southwards (mainly on the eastern side of the

Nycticeinops schlieffeni

continent) to N Namibia and KwaZulu–Natal. Extraliminally: SW Arabia. Mapped from country checklists (see order Chiroptera), Kock (1969a), other literature and museum records.

Habitat North of the Equator and south of the Sahara, found mainly in Sudanian woodlands (including woodlands dominated by *Isoberlinia* in West Africa); penetrates into more arid areas where local conditions are favourable (e.g. near rivers). South of the Equator, found in semi-desert grassland and shrubland, *Acacia–Commiphora* bushland, in wetter and drier miombo woodlands and mopane woodland, and in some coastal habitats, but not found in the most arid areas. Occurs at 1000 m on Central African Plateau in Malawi, but usually found below 900 m in southern part of its geographic range. Throughout Africa, apparently avoids forest habitats, with the exception of some riverine forests.

Abundance Uncertain. Assessed as ‘numerous in collections although not many examples from West Africa’ by Rosevear (1965), uncommon in Nigeria (Happold 1987) and ‘uncommonly recorded’ in Malawi (Happold & Happold 1997).

Adaptations Aspect ratio low; wing-loading very low. Flight fast or slow with great manoeuvrability; can take off from ground; cannot hover. Turns usually by banking (minimum radius <25 cm); occasionally by stalling-and-twisting; individuals sustained flight within a 1×1×1 m enclosure for up to three circuits/flight (4 bats, 10 flights each; M. Happold unpubl.). Cursorial locomotion slow and awkward. Roosts by day in hollow branches, rock crevices and in cracks and crevices inside hollow trees, roofs and cellars (Rosevear 1965, Pienaar *et al.* 1980, Happold *et al.* 1987). Has been found roosting in a cellar with *Coleura afra* (Anderson in Rosevear 1965) and, once, in a narrow crevice in a branch together with 12 *Tadarida demonstrator* and two *T. midas* (Verschuren 1957). Becomes torpid during day at ambient temperatures 21–24°C. In Sudan, drinks from small expanses of water soon after sundown (Kock 1969a). Captive bats, fed on winged termites, did not drink; predicted mean maximum urine concentration comparatively very high (4562 mOsmol/kg) (Happold & Happold 1988).

Foraging and Food Forages by slow-hawking, mostly 2–6 m above ground, in moderately cluttered spaces between tree trunks and between canopies, and in more open spaces in clearings, over flood-plains and over water (Fenton & Thomas 1980, Pienaar *et al.* 1980, M. Happold unpubl.). Occasionally enters houses while foraging (Rosevear 1965). Apparently feeds opportunistically on a wide variety of small insects. In Sudan, mainly small Lepidoptera and Coleoptera (Kock 1969a). In Zimbabwe (wet season), mainly Coleoptera; also Diptera, Lepidoptera and Hemiptera (dry season), Coleoptera (50% by weight); also Trichoptera and Lepidoptera (Fenton & Thomas 1980). In Kruger N. P., South Africa, mainly Coleoptera but also Diptera, Hymenoptera and Trichoptera (Aldridge & Rautenbach 1987).

Echolocation Search-phase call-shape (Malawi) smooth steep/shallow FM (Figure 118i). Intensity high; start-frequency 46–64 kHz; end-frequency 38–43 kHz; peak-frequency 38–41 kHz; call-duration mostly 7–9 ms (two tethered bats flying in open; M.

Happold unpubl.). When flying closer to ground, call-shape becomes steep FM/QCF (Figure 118j); start-frequency up to 76 kHz; end-frequency 38–42 kHz, call-duration mostly ca. 5–6 ms (two other bats, tethered; M. Happold unpubl.). In Zimbabwe, call-shape steep FM/QCF; start-frequency 78 kHz; end-frequency 33 kHz, peak-frequency 42 kHz (three bats; Fenton & Bell 1981). In Kruger N. P., South Africa, the calls of 20 released and light-tagged bats were the same as the bats from Zimbabwe (Aldridge & Rautenbach 1987). In Swaziland, call-shape steep FM; start-frequency (mean ± S.D.) 45.5 ± 0.7 kHz; end-frequency 39.5 ± 0.2 kHz, peak-frequency 41.0 ± 1.0 kHz; call-duration 3.7 ± 0.6 ms (three bats, flying in open; Taylor 1999a).

Social and Reproductive Behaviour Numbers occasionally congregate to forage (Smithers 1983). Reported to roost singly, in pairs or in small groups (Rosevear 1965, Smithers & Lobão Tello 1976), and in large numbers (Rautenbach 1982). A maternity colony containing at least 40 post-lactating ♀♀ and their young was found in the roof of a house in Malawi (Happold *et al.* 1987).

Reproduction and Population Structure Litter-size: 1–3 (details below). Reproductive chronology at 02°18'S (Masalani, Kenya): restricted seasonal monoestry; births in short wet season (Nov); litter-size 2, 3 (n = 2) (O'Shea & Vaughan 1980). At 15–16°S in Malawi: restricted seasonal monoestry with births in wet season (Nov–Dec); litter-size 2.4 (2–3), n = 5 (Happold & Happold 1990a). At 22°25'S (Kruger N. P., South Africa): restricted seasonal monoestry; births in summer (Nov–Dec [mainly Nov]) (van der Merwe & Rautenbach 1987). Spermatogenesis extends over 10 months; spermatozoa in epididymides from end Apr to early Sep. Copulation begins in early winter (Jun). Females store spermatozoa in uterine horns from then until ovulation occurs at end Aug. Gestation ca. 11 weeks. Up to five conceptuses but some reabsorbed; litter-size 2.8 (1–3), n = 11 (van der Merwe & Rautenbach 1986).

Predators, Parasites and Diseases Predators include Bat Hawks *Macheiramphus alcinus* (Fenton *et al.* 1978). Ectoparasites include a bed-bug *Aphrania elongata* (Hemiptera: Cimicidae); fleas *Lagaropsylla consularis*, *L. idae* (Siphonaptera: Ischnopsyllidae); a bat-fly *Basilia robusta* (Diptera: Nycteribiidae); and a mite *Chelanyssus aethiopicus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

GENUS *Otonycteris* Hemprich's Desert Bat

Otonycteris Peters, 1859. Monatsb. K. Preuss. Akad. Wiss. Berlin 1859: 223. Type species: *Otonycteris hemprichii* Peters, 1859.

Until 2010, considered to be a monotypic genus distributed in deserts from North Africa to Arabia, SW Asia and Central Asia (but see below). Diagnostic combination of characters: four upper and five lower cheekteeth and one upper incisor on each side (cf. *Laephotis*); ears very long (30–41 mm) but not joined at base (cf. *Plecotus*); dental formula $\frac{1113}{3123} = 30$. Selected characters of *Otonycteris hemprichii* are illustrated in Figure 134. Placed in tribe Plecotini, with *Plecotus* and *Barbastella*, on basis of bacular morphology (Hill & Harrison 1987) and chromosomal characters (Horáček 1991, Qumsiyeh & Bickham 1993). In contrast, Koopman (1994) places *Otonycteris* in tribe Nycticeini. Hooper & Van Den Bussche (2003) keep the position of the genus within the Vespertilioninae uncertain

Otonycteris hemprichii.

Figure 134. *Otonycteris hemprichii*. Flight membranes, and bones of wing, hindlimb and tail. Frontal view of head showing long, widely-separated ears. Left tragus. Skull (ZFMK 97.148).

suggesting possible relations to *Antrozoini*. Nevertheless, Simmons (2005) placed it in tribe *Plecotini*, the solution recently supported also by strong molecular evidence (Roehrs *et al.* 2010). Placed in tribe *Plecotini* by Simmons (2005). In most characters, *Otonycteris* is quite unique among the extant *Vespertilioninae*.

Since this profile and the following species profile were submitted, Benda & Gvozdk (2010) concluded that *Otonycteris* contained three

subspecies: *O. h. hemprichii* in North Africa and extralimally in Levant and Mesopotamia, *O. h. cinerea* and *O. h. jin* both extralimally only, and an additional species, *O. leucophaea* (Severcov, 1873), found extralimally in Asia.

The only species in Africa is *Otonycteris hemprichii*.

Meredith Happold

Otonycteris hemprichii HEMPRICH'S DESERT BAT

Fr. Oreillard d'Hemprich; Ger. Hempriches Wüstengroßohr

Otonycteris hemprichii Peters, 1859. Monatsber. K. Preuss. Akad. Wiss. Berlin 1859: 233. Type locality: not stated; most probably Nile Valley south of Aswan, Egypt (Kock 1969a).

Taxonomy In Africa, monotypic with the nominate subspecies (but see Geographic Variation). Synonyms in Africa: *saharae*, *ustus*. Chromosome number (Israel): $2n = 28$; $aFN = 46$ (Qumsiyeh & Bickham 1993). For molecular data (cyt b, ND 1) and variation in morphometric characters, see Benda and Gvoždík (2010).

Description Medium-small, robustly built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, long for a vespertilionid (30–41 mm). Sexes similar. Pelage loose, soft; ventral pelage less dense; mid-dorsal hairs 9–12 mm. Dorsal pelage pale beige; hairs off-white with beige to pale beige at tip. Ventral pelage whitish to pure white. Muzzle fairly long and narrow. Ears yellowish-brown, long for a vespertilionid (30–41 mm) and of medium relative length (55.7 [52–60]% of FA); well separated; inner and outer margins smoothly convex; tip rounded (Figure 134). Antitragus very small. Tragus long, tapering to blunt point. Eyes fairly large for a microbat. Two pairs of pectoral nipples (cf. one pair in all other African bats). Wings very broad; fifth finger longer than fourth. Wings and interfemoral membrane thick and leathery, semi-translucent, pale yellowish-brown near body, becoming pale greyish-brown and then whitish around wing-tips and posterior edges. Tail moderately long (72.7 [66–86]% of HB, $n = 27$). Interfemoral membrane broad; calcar reaching less than half-way to tip of tail. Tibia 38.6 (35–43)% of FA, $n = 5$. Penis very unusual in form – the glans is expanded dorsoventrally and protrudes through two lateral swellings, and there is a third swelling on the dorsal surface of the penis.

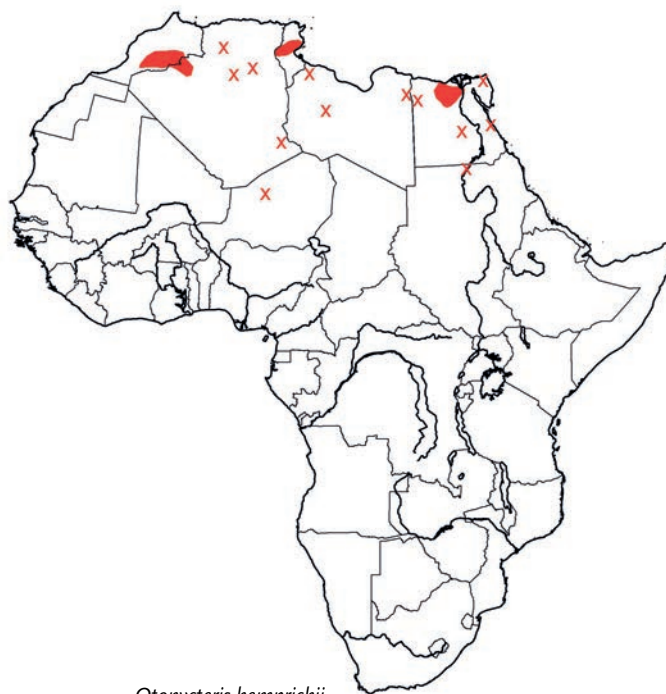

Skull (Figure 134) robust with braincase elongated; rostrum broad and high; interorbital constriction narrow. Dentition robust and long. Upper incisor unicuspid, sharp and caniniform. Canine large, round in transverse section. Upper premolar large and caniniform, comparatively higher than the molars. M^3 and talonid of M_3 extremely reduced in comparison with other bats. Lower incisors small, bicuspid, compressed and partly overlapping; outer lower incisors (I_3) with small cusp on lingual side. Anterior lower premolar small, within toothrow; lower canine and posterior premolar not in contact. Lower molars myotodont.

Geographic Variation In Africa, there is clinal variation in size and colouration from west to east; individuals from north-west are on average slightly smaller and are paler (dorsal pelage

almost white). Some authors (e.g. Koopman 1994) recognize up to five subspecies, of which only *O. h. hemprichii* occurs in Africa. However, the overall pattern of geographical variation seems to be clinal rather than categorical, and therefore the species is currently considered monotypic (Kock 1969a, Horáček 1991, Kowalski & Rzebik-Kowalska 1991). Nevertheless, Benda & Gvoždík (2010) demonstrated that the latitudinal W–E cline is associated with strong phylogeographic substructures suggesting a categorical variation. Consequently, besides the nominate subspecies (Morocco to Levant) they distinguish two eastern subspecies of *O. hemprichii* (*cinerea* in C Iran and Oman, *jin* in SE Iran) and separate the Central Asiatic populations into a distinct species *O. leucophaea* (Severcov, 1873).

Similar Species Only three other vespertilionids in Africa have ears that are long for an African vespertilionid (>28 mm):

Plecotus (3 spp). Much smaller (FA: <43 mm; GLS: <18 mm). Ears with inner margins joined at base by low frontal band. Five upper and six lower cheekteeth and two upper incisors on each side.

Otonycteris hemprichii

Distribution In Africa, recorded from the Sahara Arid BZ and marginally in the southern fringe of the Mediterranean Coastal BZ, from W Morocco to Egypt and southwards to N Niger and N Sudan. Extraliminally: Arabia and SW Asia to Tajikistan, N Pakistan and Kashmir.

Habitat Rocky deserts covered with a sparse xeric herbaceous vegetation.

Abundance Among the rarest and the least known species in almost all parts of its geographic range, although may be found quite regularly in some localities (e.g. where rocky cliffs are present).

Adaptations Aspect ratio low; wing-loading low. Flight slow and 'floppy' (Nowak 1999). By day, has been found roosting in rock-fissures and similar places in buildings, e.g. cracks in the stone walls of deserted buildings (Harrison & Bates 1991, Gharaibeh & Qumsiyeh 1995). Apparently well adapted to desert habitats, heterothermic and capable of hibernating (evident in C Asia). Daniel *et al.* (2010) observed in Negev Desert, Israel, that ♀♀ often used both deep and shallow daily torpor during the first two trimesters of pregnancy, with body temperature frequently dropping as low as 15 °C. During the last trimester of pregnancy and during nursing, the bats used only shallow torpor, with body temperature always >29 °C.

Foraging and Food Apparently feeds opportunistically on non-flying prey, which is gleaned from the ground. In Sep in C Asia, feeds mainly on grasshoppers and crickets (Orthoptera), scorpions and spiders (Solifugidae) (Arlettaz *et al.* 1995). In Israel, the diet is mainly Coleoptera, Heteroptera and Diptera (Fenton *et al.* 1999); sometimes only Coleoptera of the family Scarabaeidae (Whitaker *et al.* 1994). Based on wing morphology, Norberg & Fenton (1988) predict that this species also feeds on small vertebrates but, although geckos have been eaten by captive bats, there is no evidence that vertebrate prey is taken in the wild. Typically, these bats emerge ca. 40 minutes after sunset (Fenton *et al.* 1999) and fly slowly over rocky terrain, staying within 40–100 cm of the ground (Arlettaz *et al.* 1995). When prey is detected, the bat lands briefly to attack and collect its prey, and then eats on the wing while flying and mainly gliding slowly in wide circles 3–7 m above ground. These bats do not forage from perches. When foraging close to the ground, echolocating sometimes ceases, suggesting that non-flying prey can be located by alternative methods (perhaps visually or by detecting sounds made by the prey). Daniel (2005) found in Negev Desert, Israel, that the diet was composed of Coleoptera, Chilopoda, Scorpiones, Aranae and Soliphugae with certain seasonal variation. Feeding on scorpions (up to more than 70% of the diet in August) was analysed in detail by Holderied *et al.* (2011). The scorpions are located by passive listening. No evidence of risk-sensitive prey selection was found, bats were frequently stung during predatory action without any change in the bats' behaviour and also without any signs of poisoning. In the Negev Desert, Israel, the distance between roosts and foraging sites varied from 0.5 to 9 km; daily foraging time, mean daily foraging bout length, and first daily foraging bout length were all significantly and positively correlated with distance between the roost and the foraging site, which support the prediction that *O. hemprichii* is a 'central-place forager' (Daniel *et al.* 2008).

Echolocation Search-phase call-shape shallow FM. Intensity high; start-frequency 40 kHz; end-frequency 18 kHz; peak-frequency 30–32 kHz; second harmonic with half intensity of first; third harmonic weak; call repetition rate comparatively slow and regular (Horáček 1991). Holderied *et al.* (2011) reports that during a searching flight (with average speed 3.52 m/s) *O. hemprichii* emits multiharmonic calls of a low intensity with peak frequency of upper harmonic 54.45 kHz and peak frequency of lower harmonics 29.96 kHz. Average pulse duration was 2.46 ms with 131 ms pulse interval.

Social and Reproductive Behaviour Little is known. Males appear to roost singly. Maternity colonies of 3–18 ♀♀ were recorded by Bogdanov (1953). Radio-tracking revealed frequent changes in day-roosts (Fenton *et al.* 1999).

Reproduction and Population Structure Litter-size (extraliminally): 2 (n = 9) (Attalah 1977, Horáček 1991). Reproductive chronology not known in Africa or extraliminally. In Niger, 2 of 3 ♀♀ were lactating in mid-Jun (Fairon 1980). For extralimital records, see Gharaibeh & Qumsiyeh (1995).

Predators, Parasites and Diseases Remains have been found in pellets of Pharaoh Eagle-owl *Bubo ascalaphus* in Morocco (Aulagnier 1989) and Barn Owl *Tyto alba* in Algeria (Kowalski & Rzebiak-Kowalska 1991). Ectoparasites include ticks *Argas hermanni*, *A. transgarepinus*, *Carios vespertilionis*, *C. boueti*, *C. confusus* (Acari: Argasidae) and a mite *Rodhainyssus myotis* (Acari: Gastronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern (assessed from African and extralimital data).

Little is known about populations of these bats and their potential threats remain unclear.

GENUS *Pipistrellus*

Pipistrelles

Pipistrellus Kaup, 1829. Skizz. Entwickel.-Gesch. Nat. Syst. Europ. Thierwelt 1: 98. Type species: *Vesperilio pipistrellus* Schreber, 1774.

As defined by Hill & Harrison (1987), *Pipistrellus* is a large genus with ca. 79 species of which 28 occur in Africa (at least two of these probably contain more than one species). In contrast, Simmons (2005) recognizes only 31 species in *Pipistrellus*, the remainder having been placed in five other genera, of which two (*Neoromicia* and *Hypsugo*) are represented in Africa. For reasons given below, this treatment is not followed here. Diagnostic combination of characters for species found in Africa: four or five upper cheekteeth, five lower cheekteeth and two upper incisors on each side; ears short and not joined at base; fifth finger not shortened (considerably longer than metacarpals of third and fourth fingers) (cf. *Nyctalus*); no body pattern; wings not reticulated but sometimes with white or pale margin along the posterior edge, which is referred to as a hind-border; outer margin of ear not reaching mouth; lower lip without lobe near posterior angle (cf. *Glauconycteris*); FA: <40 mm. Most species (possibly all) have a glandular swelling on each side of the muzzle and a buccal gland (= buccal pad) on the inside of each corner of the mouth; these glands change in size and prominence probably in conjunction with reproductive condition. Most species of *Pipistrellus* have five upper cheekteeth of which two are premolars. However, in some species, the anterior upper premolar (P^2) is minute and often not visible above the gum, or it can be absent. Although those species of *Pipistrellus* with only four visible upper cheekteeth strongly resemble species of *Eptesicus*, all African *Pipistrellus* are smaller (FA: 23–39 mm; GLS: 10.0–15.0 mm) than all African *Eptesicus* (FA: 38–54 mm; GLS: 15.3–21.5 mm) with the exception of *E. floweri* (FA: 34–38 mm; GLS: 12.0–13.5 mm). Selected external and craniodental characters of *Pipistrellus* are illustrated in Figure 135, and bacula of most species are illustrated in Figures 139, 140 and 141.

Traditionally, *Pipistrellus* and *Eptesicus* were distinguished by the presence or absence, respectively, of the anterior upper premolar. However, this proved unsatisfactory and phylogenetically invalid, mainly because reduction in teeth apparently occurred independently in several lineages of the Vespertilionidae. The baculum is considered to be a more conservative character than teeth and, based on bacular morphology, Hill & Harrison (1987) removed many species from *Eptesicus* to *Pipistrellus*. At the same time, they divided *Pipistrellus* into seven subgenera of which three, *P. (Pipistrellus)*, *P. (Hypsugo)* and *P. (Neoromicia)*, are represented in Africa. Subsequently, there have been other investigations based on chromosomes and DNA. Unfortunately, the systematics of many of the species in *Pipistrellus*, as defined above, is controversial – studies based on different criteria lead to different conclusions. A brief summary of some of the major proposals is as follows. (1) Based mainly on cranial characters, Koopman (1993) considered *Neoromicia* to be a subgenus of *Eptesicus* rather than *Pipistrellus*. (2) Based on morphological characters, *Hypsugo* was raised to generic status by Horáček & Hanák (1986), and this is supported by the biochemistry of the type species *H. savii* (Ruedi & Arlettaz 1991), by chromosomal characteristics (e.g. Volleth & Heller 1994) and by mitochondrial DNA characters (Hoofer & Van Den Bussche 2003). (3) Based on dental morphology of both extant and fossil forms, Menu (1987) placed the African species examined by him into three genera (*Pipistrellus*, *Hypsugo* and

Figure 135. African *Pipistrellus* (*sensu lato*). Flight membranes, and bones of wing, hindlimb and tail (e.g. *Pipistrellus nanus* from Malawi). Skull of *Pipistrellus nanus* (HC 2870, Malawi).

Nycterikaupius) and a collective group referred to as *Attalepharca*. (4) On the basis of chromosomal characters, *Neoromicia* was raised to generic status by Volleth *et al.* (2001), and the African species, for which chromosomal data were available, were reclassified into the genera *Pipistrellus*, *Hypsugo* and *Neoromicia* (Heller *et al.* 1994, Volleth *et al.* 2001, Kearney *et al.* 2002, M. Volleth pers. comm.). (5) On

the basis of mitochondrial DNA, Hofer & Van Den Bussche (2003) questioned the definitions of *Hypsugo* and *Neoromicia* and, pending further studies, restricted *Hypsugo* to the type species, *H. savii*, and restricted *Neoromicia* to the type species, *N. somalicus*.

Although the generic status of *Hypsugo* and *Neoromicia* appears to be justified, it is not possible to distinguish these genera from each other, and from *Pipistrellus* (*sensu stricto*), on the basis of external characters that can be checked by examining living or whole specimens. Furthermore, these genera cannot, as yet, be diagnosed consistently by morphological, bacular, dental, chromosomal or molecular characters and, consequently, the species compositions of these taxa are very controversial. Also, it has not yet been possible to investigate the chromosomes, biochemistry and DNA of several species, so that their placement in *Neoromicia* or *Hypsugo* is largely guesswork based on morphological criteria. To avoid complications arising from these controversies, and pending a thorough revision of these species, we tentatively follow Hill & Harrison (1987) – and also Koopman (1994) and Nowak (1999) – in considering all of the African pipistrelle-like species to be members of the genus *Pipistrellus*. However, the traditional classification and subsequent alternative possibilities are given in the profiles of each of these species. As conventional, subgenus names are given in brackets, e.g. *Pipistrellus* (*Neoromicia*) *capensis* or *P. (Neoromicia) capensis*.

Pipistrellus, as defined by Hill & Harrison (1987), is very widely distributed in the tropical, sub-tropical and temperate regions of Africa, Europe, Asia, the South-East Asian islands, Australia and North America as far south as Honduras. In Africa, four species are found mainly or only in rainforest, eight mainly in savanna habitats, nine in both forest and savanna habitats, two in both savanna and arid habitats, and four mainly in the Mediterranean Coastal BZ. The true habitat of one species, *P. permixtus*, is not known.

Distinguishing the African species in the genus *Pipistrellus* is not easy and seldom possible without examining skull and dental characters. Some of the most useful distinguishing characters are:

Wing colour: can be white, pale (various shades of pale brown) or dark (various shades of dark brown to almost black).

Hind-border: said to be present when part or all of the posterior edge of the wing-membrane is white or pale; it can be broad or narrow.

Hairs of dorsal and ventral pelage: can be unicoloured, bicoloured or tricoloured.

Tragus: the following characters are often useful: (a) level of broadest part (can be above, at, or below mid-height, 'mid-height' being half-way along the length of the posterior margin of the tragus), (b) anterior margin (straight or concave), (c) posterior margin (said to be 'smoothly convex' when it is smoothly convex either for its entire length or between the tip of the tragus and the top of the basal lobe, or 'with abrupt angle' when there is a distinct, obtuse angle in the margin [excluding any angles associated with a basal lobe]), (e) tip (rounded, angular, or bluntly pointed) (Figure 136). The approximate length of the tragus relative to the length of the ear is mentioned in most profiles but, because this ratio may be distorted in preserved specimens, accurate estimates of relative length are seldom available. Tragi of 16 species are illustrated in Figure 136.

Skull: skulls vary (amongst other things) in size, robustness, the extent to which the braincase is elevated and broadened, the extent to which the rostrum is lengthened, broadened and/or flattened, and the extent to which the lambdoid and/or posterior sagittal crests are developed to form a low occipital helmet. In African *Pipistrellus*, mean GLS ranges from 11.0 to 14.5 mm, so 11.0–12.2 mm is small, 12.3–13.3 mm is medium and 13.4–14.5 mm is large. Five aspects of skull shape are covered in the *Pipistrellus* species profiles:

Braincase height as percentage of GLS (height measured over the bullae) (Table 25): means (excluding that of *P. pipistrellus* for which there are no African data) range from 39.2 to 48.1%, therefore 39.2–42.2% is relatively low, 42.3–45.1% is medium, and 45.2–48.1% is relatively high. Data in all profiles are from V. Van Cakenbergh (unpubl.).

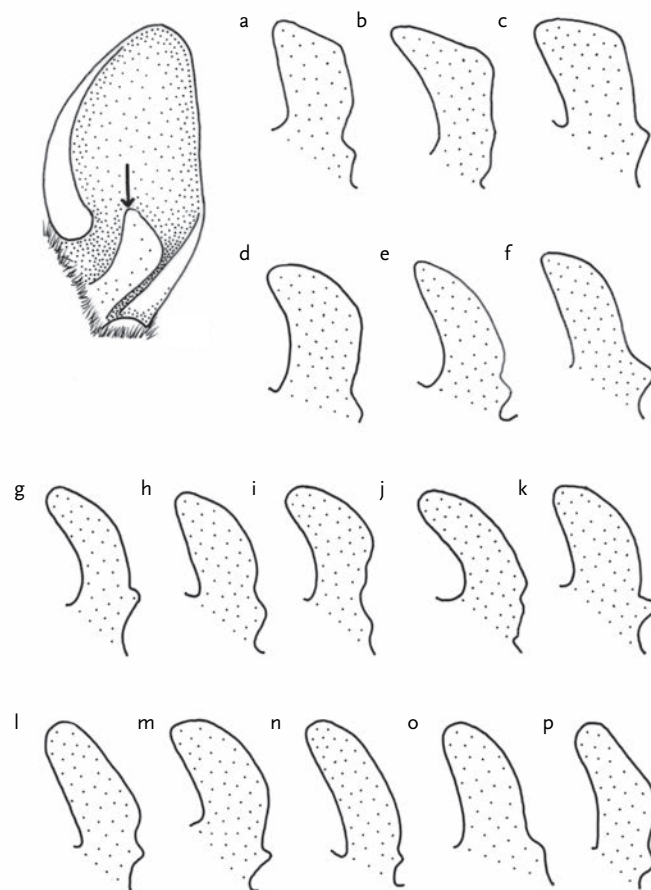

Figure 136. Left ear and tragus of *Pipistrellus nanus* and tragi of some other African species of *Pipistrellus* (*sensu lato*). The posterior margin of the tragus, above the basal notch, is described as 'having an abrupt angle' in (a) *P. brunneus* (holotype), (b) the 'hatchet-shaped' tragus of *P. nanus* (syntype), (c) the tragus of *P. tenuipinnis* (and also that of *P. cf. helios* [not illustrated]). The posterior margin, above the basal notch, is described as 'smoothly convex' in (d) *P. ariel*, (e) *P. capensis*, (f) *P. crassulus bellieri*, (g) *P. guineensis*, (h) *P. hesperidus*, (i) *P. inexpectatus*, (j) *P. cf. melckorum*, (k) *P. nanulus* (holotype), (l) *P. pipistrellus*, (m) *P. rendalli* (holotype), (n) *P. rueppellii*, (o) *P. rusticus*, (p) *P. somalicus* and other species. Arrow points to tip of tragus. (d) based on Makin & Harrison (1988); (b), (i), (k) and (m), based on Rosevear (1965); (o) based on photo by T. Kearney; (e), (h), (j) and (n) based on camera lucida drawings of fresh specimens: all others based on camera lucida drawings of well-preserved specimens in alcohol. All tragi drawn to same size.

Table 25. Relative heights and breadths of braincase, relative breadth of interorbital constriction and relative lengths and breadths of rostrum for African *Pipistrellus*. For each species, relative braincase height (measured over bullae) and breadth (measured at onset of zygomatic arches) are given as percentages of greatest length of skull (GLS). Interorbital breadth is given as percentage of GLS. Relative rostral length is estimated from C–M³ (alveolar) as percentage of GLS. Relative rostral breadth is estimated from the width across the canines (C¹–C¹) as percentage of GLS. H = high, M = medium, L = low or long, S = short, B = broad, N = narrow (these terms referring to relative parameters in all cases; for definitions see genus *Pipistrellus*). All data from V. Van Cakenberghe (unpubl.). All data are from African specimens except where indicated by asterisk. No data are available for the only known specimen of *P. permixtus*.

Braincase breadth as percentage of GLS (breadth measured at onset of zygomatic arches) (Table 25): means range from 47.0 to 53.5%, therefore 47.0–49.2% is relatively narrow, 49.3–51.3% is medium, and 51.4–53.5% is relatively broad. Data in all profiles from V. Van Cakenberghe (unpubl.).

Interorbital breadth as percentage of GLS: means range from 26.1 to 33.7%, therefore 26.1–28.6% is relatively narrow, 28.7–31.2% is medium, and 31.3–33.7% is relatively broad. Data in all profiles from V. Van Cakenberghe (unpubl.).

Rostral shape: varies in relative breadth and length. Relative length has been estimated from C–M³ as percentage of GLS: means range from 34.4 to 37.0%, therefore 34.4–34.9% is relatively short, 35.0–35.8% is medium, and 35.9–37.0% is relatively long. Relative breadth has been estimated from C¹–C¹ (distance across the upper canines, measured from the outer side of each canine at alveolar level) as percentage of GLS: means range from 29.9 to 34.5%, therefore 29.9–31.4% is relatively narrow, 31.5–33.0% is medium, and 33.1–34.5% is relatively broad. Data in all profiles from V. Van Cakenberghe (unpubl.).

Forehead region of skull: the profile (viewed laterally) of the forehead region (i.e. that part of the profile encompassing most of the rostrum and the anterior part of the braincase) can be strongly concave, moderately concave, weakly concave, or straight (or almost straight) depending on the extent to which the frontal region is inflated and raised above the plane of the rostrum (Figure 137); the variation is gradual and the boundaries between these categories are not clearly demarcated. Note that, in *Pipistrellus*, the concavity, even when maximal as in ‘strongly concave’, is not as strongly concave as, for example, in *Kerivoula* and *Miniopterus*.

Anterior upper premolar: present or absent; well developed, medium or minute relative to the size of the posterior premolar (assessed

Figure 137. Range of variation in the degree of concavity of the dorsal profile of the forehead region (viewed laterally) in African *Eptesicus* and *Pipistrellus* (*sensu lato*). (a) Strongly concave (e.g. *P. nanus*; HC 2870). (b) Moderately concave (e.g. *P. hanaki*, based on Benda *et al.* 2004b). (c) Weakly concave (e.g. *P. guineensis*; ZFMK 73.23). (d) Straight (or almost straight) (e.g. *P. crassulus bellieri*; holotype, RMCA RG 35686).

qualitatively); visible or not visible above gum; in tooththrow or displaced lingually. Note that the anterior upper premolar is always much smaller than the posterior upper premolar and that the above size categories have been established solely to enable the relative sizes of the anterior premolars of African species of *Pipistrellus* to be compared with each other.

Inner upper incisor: may be unicuspid or bicuspid. However, weakly bicuspid teeth may appear unicuspid after wearing.

Lower molars: may be myotodont or nyctalodont (Figure 138). Myotodont lower molars are characterized by the path of the postcristid ridge, which directly connects the hypoconid cusp with the entoconid cusp, leaving the hypoconulid isolated. Nyctalodont lower molars are characterized by the path of the postcristid ridge, which connects the hypoconid cusp with the hypoconulid without reaching the entoconid cusp, or which runs into the gap between the

Figure 138. Myotodont and nyctalodont lower molars of vespertilionid bats: these are distinguished by differences in the path of the postcristid ridge (broad dashed line) in relation to the entoconid cusp and the hypoconulid. (a) Occlusal view of a myotodont lower molar, with anterior side uppermost and labial side on left, showing the postcristid ridge connecting the hypoconid cusp and entoconid cusp, leaving the hypoconulid isolated. (b) Occlusal view of a nyctalodont lower molar, showing the postcristid ridge connecting the hypoconid cusp with the hypoconulid or running into the gap between the hypoconulid and the side of the molar. (c) Myotodont lower molar viewed from the labial (outer) side (with anterior side on left). (d) Nyctalodont lower molar viewed from the labial side showing (in this case) the postcristid ridge running into the gap between the hypoconulid and the molar. Cusps indicated by open circles; ridges by narrow or broad dashed lines. PR = postcristid ridge, HC = hypoconid cusp, EC = entoconid cusp, H = hypoconulid.

hypoconulid and the side of the molar. A high-quality binocular microscope is necessary to distinguish myotodont and nyctalodont molars accurately, especially for small species.

Bacular morphology: also useful diagnostically (Figures 139, 140 and 141).

Based on the shape of the lower molars, African *Pipistrellus* can be divided into the myotodont group and nyctalodont group, and then the species within each group can usually be distinguished by the characters given in Tables 26 and 27, respectively. These are not necessarily species-groups in the systematic sense, but it is noteworthy that all African species placed in *Neoromicia* and *Hypsugo* by Simmons (2005) have myotodont lower molars with the exception of *P. nanus*, and all African species placed in *Pipistrellus* by Simmons (2005) have nyctalodont lower molars. Because of this, we have strong doubts about the assignment of *P. nanus* to either *Hypsugo* or *Neoromicia*, and retain it in *Pipistrellus* (*sensu stricto*). Where the tabulated information fails to distinguish very similar species, see 'Similar Species' in the relevant profiles. In the Similar Species sections, comparisons are made only between species of *Pipistrellus* and *Eptesicus* that occur in Africa (with very few exceptions).

The species are presented in alphabetical order irrespective of any relationships between them.

Victor Van Cakenberghe & Meredith Happold

Figure 139. Bacula of ten species of *Pipistrellus* (*sensu stricto*) occurring in Africa. (a) *P. aero* (lateral view is of left side reversed). (b) *P. deserti*. (c) *P. hanaki* (lateral view is of left side reversed). (d) *P. hesperidus*. (e) *P. kuhlii* from Greece. (f) *P. nanulus*. (g) *P. nanus*. (h) *P. pipistrellus* (lateral view is of left side reversed). (i) *P. rueppellii* from Uganda. (j) *P. rueppellii pulcher* (holotype) from Zanzibar. (k) *P. rusticus*. (l) *P. rusticus*. Based on bacular morphology, *P. nanus* was placed *P. (Hypsugo)* by Hill & Harrison (1987), but is retained in *Pipistrellus* (*sensu stricto*) here (see profile). For each species, left illustration is dorsal view with tip uppermost, right illustration is lateral view of the right side unless stated otherwise. Figs: (a) based on Lavrenchenko *et al.* (2004), (c) and (h) based on Benda *et al.* (2004b), (d) and (l) adapted from Kearney *et al.* (2002); all others based on Hill & Harrison (1987). Bacula drawn to same size (for scale drawings, see sources cited above).

Figure 140. Bacula of four species of *Pipistrellus* (*sensu lato*), occurring in Africa, that are placed in *P. (Hypsugo)* by Hill & Harrison (1987) on basis of bacula morphology, and *P. crassulus*, which was placed in *P. (Pipistrellus)* by Hill & Harrison (1987) but subsequently placed in *Hypsugo* by Heller *et al.* (1994) and others (see profile). (a) *P. anchietae* (views: dorsal and left ventro-lateral reversed). (b) *P. anchietae* (syntype of *Vesperus bicolor*). (c) *P. ariel* (based on Makin & Harrison 1988). (d) *P. crassulus* (dorsal view only). (e) *P. eisentrauti* (BMNH 84.1686 from Mt Cameroun). (f) *P. savii*. For each species except (a), left illustration is dorsal view with tip uppermost, right illustration is lateral view of right side. (c) based on Makin & Harrison 1988; all others based on Hill & Harrison (1987). Bacula drawn to same size (for scale drawings, see sources cited above).

Figure 141. Bacula of seven species of *Pipistrellus* (*sensu lato*) that are placed in *P. (Neoromicia)* by Hill & Harrison (1987) on basis of bacula morphology, and also *P. cf. helios* which is placed in *P. (Hypsugo)* by Hill & Harrison (1987) but in *Neoromicia* by Simmons (2005, as *N. helios*). (a) *P. capensis* from Ghana. (b) *P. capensis* from Ethiopia. (c) *P. guineensis*. (d) *P. cf. helios*. (e) *P. cf. melckorum* from Zimbabwe (Hill & Harrison 1987 as *P. melckorum*). (f) *P. cf. melckorum* (adapted from Kearney *et al.* 2002 as *Neoromicia cf. melckorum*). (g) *P. rendalli*. (h) *P. somalicus*. (i) *P. tenuipinnis*. (j) *P. zuluensis*. (k) *P. zuluensis* (adapted from Kearney *et al.* 2002 as *Neoromicia zuluensis*). All except (f) and (k) are based on Hill & Harrison (1987).

Table 26. Key to the African species of the genus *Pipistrellus* (*sensu lato*) that have myotodont lower molars. Most of these species have only one upper premolar, the anterior premolar being absent. In some species, the anterior upper premolar may be present, but small or minute, difficult to see because it is displaced lingually from the toothrow (sometimes resulting in the canine and posterior premolar being in contact), or not visible because it has not erupted through the gum. Measurements and distributions pertain only to Africa.

| Wing colour | Inner upper incisor | Dorsal hairs (Ventral hairs) | FA (mm) | Mid-ventral pelage | Anterior upper premolar
If present, size and visibility above gum | |
|-------------|---------------------------------------|---|---------------------------|---|---|--|
| White | Unicuspid | Bicoloured or tricoloured (Bicoloured) | 33.7 (29–37) | Cream, whitish or pale grey | Absent | |
| White | Weakly bicuspid | Usually unicoloured (Bicoloured) | 29.8 (28–33) | Whitish or cream | Sometimes present
If present: minute, usually visible | |
| Dark | Unicuspid | Unicoloured (Bicoloured) | 34.9 (33–38) | Pale greyish-brown to medium brown | Absent | |
| Dark | Unicuspid | Bicoloured (Bicoloured) | 29.1 (30–31) | Greyish-cream | Minute, sometimes not visible | |
| Dark | Unicuspid or weakly bicuspid | Bicoloured (Bicoloured) | 37.1 (36–39) ^b | Brownish-cream | Absent | |
| Dark | Weakly bicuspid (unicuspid when worn) | Bicoloured (Bicoloured) | 31.9 (28–38) | White, whitish, cream or buff | Absent except extremely rarely, in which case, minute, not visible | |
| Dark | Usually unicuspid | Bicoloured or tricoloured (Bicoloured) | 29.9 (27–33) | Pale greyish-brown or brown | Absent except extremely rarely, in which case, minute, hardly visible | |
| Dark | Usually unicuspid | Faintly bicoloured (Faintly bicoloured) | 28.8 (22–32) | Pale brown or brown | Usually absent | |
| Dark | Bicuspid | Unicoloured (Unicoloured) | 35.4 (33–38) | Pale brown, usually yellowish | Minute, sometimes not visible, sometimes absent | |
| Dark | Bicuspid | Unicoloured (Unicoloured) | 30.2 (28–32) | Dark brown or reddish-brown | Minute, barely visible or not visible | |
| Dark | Bicuspid | Unicoloured (Unicoloured) | 24.9 (23–26) | Dark umber-brown | Minute and often not visible; sometimes absent | |
| Dark | Bicuspid | Unicoloured (Bicoloured) | 30.5 (28–33) | Pale brown | Small to medium-sized, visible | |
| Dark | Bicuspid | Bicoloured (Unicoloured) | 32.0 (31–33) | Reddish-cream | Minute, usually not visible | |
| Dark | Bicuspid | Bicoloured (Bicoloured) | 34.0 (32–36) | Slightly reddish-brown tinged with beige | Minute to medium-sized, usually visible, occasionally absent | |
| Dark | Bicuspid | Bicoloured (Bicoloured) | 35.5 (34–38) | Yellowish-white or greyish-white | Minute, not visible, sometimes absent | |
| Dark | Bicuspid | Bicoloured (Bicoloured) | 31.3 (29–34) | Pale brown, cream or white | Minute, not visible | |
| Dark | Bicuspid | Bicoloured (Bicoloured) | 27.7 (23–35) | Dark to medium rust-brown, sometimes speckled | Absent | |
| Dark | Bicuspid | Tricoloured (Bicoloured) | 28.0 (26–30) | Pale brown to pale yellowish-brown | Well developed, visible | |

^a Sample less than six.

^b Data for five specimens of *P. cf. melkorum* identified from their chromosomes; for other specimens, FA: 35.3 (32–38) mm, n = 35; GLS: 14.6 (13.7–15.5) mm, n = 26 (V. Van Cakenberghe, pers. comm.).

| | Forehead region of skull | Relative height of braincase (relative breadth of braincase) | GLS (mm) | Miscellaneous | Species |
|--|-----------------------------------|--|-------------------------------|--|-------------------------|
| | Straight | Medium (Medium) | 13.3 (12.3–14.4) | Dorsal pelage pale brown, not contrasting strongly with pale wings | <i>P. rendalli</i> |
| | Weakly concave | High (Medium) | 12.3 (11.6–13.0) | Dorsal pelage blackish-brown in strong contrast to pale wings | <i>P. tenuipinnis</i> |
| | Weakly concave | High (Medium) | 13.5 (13.0–14.1) | Rainforest habitats | <i>P. brunneus</i> |
| | Strongly concave | Medium (Narrow) | 11.1, 11.3 ^a | Sahara Arid and Sahel BZs; only known from Sudan | <i>P. ariel</i> |
| | Straight to weakly concave | Low (Narrow) | 14.5 (13.8–14.9) ^b | Zambezian Woodland BZ
Tail: 39.6 (35–44) mm ^b
Occipital helmet weakly developed
Molars more massive than in <i>P. capensis</i> | <i>P. cf. melckorum</i> |
| | Straight to weakly concave | Low (Medium) | 13.5 (12.0–15.4) | Widespread south of Sahara
Tail: 30.6 (25–38) mm
Occipital helmet usually well developed
Molars less massive than in <i>P. cf. melckorum</i> | <i>P. capensis</i> |
| | Weakly to moderately concave | High (Narrow) | 12.2 (11.3–12.9) | Widespread south of 9° S, and also Kenya
Occipital helmet absent | <i>P. zuluensis</i> |
| | Weakly concave to almost straight | Medium (Medium) | 12.2 (11.3–12.9) | Widespread south of Sahara to 5° S (but seldom in Rainforest BZ); occurrence further south uncertain
Occipital helmet absent | <i>P. somalicus</i> |
| | Weakly concave to almost straight | Medium (Medium) | 14.2 (13.8–14.7) | Various BZs and Mosaics; Cameroon, Uganda, Burundi, Somalia, Angola and Malawi | <i>P. grandidieri</i> |
| | Weakly concave to almost straight | Low (Broad) | 12.8 (12.5–13.2) | Rainforest and Afroalpine–Afromontane BZs and Rainforest–Savanna Mosaics; east of 10° E | <i>P. c. crassulus</i> |
| | Weakly concave | High (Medium) | 11.0 (10.3–11.4) | Rainforest BZ and Northern Rainforest–Savanna Mosaic; West and central Africa | <i>P. musciculus</i> |
| | Straight to weakly concave | High (Broad) | 12.9 (12.1–13.6) | Rainforest BZ and Northern Rainforest–Savanna Mosaic; Guinea, Liberia, Côte d'Ivoire | <i>P. c. bellieri</i> |
| | Weakly concave to almost straight | Low (Medium) | 12.6 (12.5–12.6) ^a | Guinea Savanna BZ and Northern Rainforest–Savanna Mosaic
Wings with white hind-border | <i>P. inexpectatus</i> |
| | Very weakly concave | Medium (Medium) | 13.9 (13.7–14.1) | Afroalpine–Afromontane BZ; Cameroon
Wings without white hind-border | <i>P. eisentrauti</i> |
| | Weakly concave to almost straight | Medium (Narrow) | 14.0 (12.8–14.6) | North-west Africa; no overlap with geographic ranges of other species | <i>P. savii</i> |
| | Weakly concave | Medium (Medium) | 12.5 (11.2–13.7) | Mainly Zambezian Woodland BZ; Angola, S DR Congo, Zambia, Zimbabwe, South Africa
Wings with or without white hind-border | <i>P. anchietae</i> |
| | Weakly concave | Medium (Medium) | 11.3 (10.7–11.8) | Mainly Guinea and Sudan Savanna BZs and Rainforest–Savanna Mosaics
Wings with or without white hind-border | <i>P. guineensis</i> |
| | Strongly concave | High (Medium) | 11.0 (10.4–11.4) | Mainly Somalia–Masai Bushland BZ and Coastal Forest Mosaic; Kenya and marginally in some adjacent countries
Tragus hatchet-shaped
Usually paired glands on interfemoral membrane | <i>P. cf. helios</i> |

Table 27. Key to the African species of the genus *Pipistrellus* that have nyctalodont lower molars. All of these species (except *P. rusticus*) have two upper premolars on each side, but the anterior upper premolar is often minute and difficult to see because it is displaced lingually from the toothrow (sometimes resulting in the canine and posterior premolar being in contact), or not visible because it has not erupted through the gum (see genus *Pipistrellus* for explanation of the size categories). In *P. rusticus*, one or both anterior upper premolars is sometimes absent. Measurements and distributions pertain only to Africa.

| Ventral pelage pure white | Tragus with sharp angle on posterior border | Inner upper incisor | Dorsal hairs (Ventral hairs) | White hind-border on wing | Colour of dorsal pelage | |
|---------------------------|---|---------------------|-----------------------------------|---|--|--|
| Yes | No | Bicuspid | Bicoloured (Unicoloured) | Sometimes present | Grey to sepia brown | |
| No | Yes | Usually bicuspid | Bicoloured (Bicoloured) | Absent | Chocolate brown or sepia brown, sometimes with gold sheen | |
| No | No | Bicuspid | Unicoloured (Usually unicoloured) | Usually absent | Reddish-brown | |
| No | No | Bicuspid | Bicoloured (Bicoloured) | Absent | Brown to rusty-brown | |
| No | No | Bicuspid | Bicoloured (Bicoloured) | Absent (pale hind-border sometimes present) | Pale brownish to greyish-brown | |
| No | No | Bicuspid | Bicoloured (Not known) | No data | Not known | |
| No | No | Unicuspid | Bicoloured (Bicoloured) | Present | Pale sepia brown to pale yellowish-brown, sometimes with greenish tint | |
| No | No | Unicuspid | Bicoloured (Bicoloured) | Present | Sepia brown, dark rusty-brown to pale yellowish-brown | |
| No | No | Unicuspid | Bicoloured (Bicoloured) | Absent | Dark, slightly reddish-brown | |
| No | No | Unicuspid | Bicoloured (Bicoloured) | Sometimes present | Reddish-brown, orange-brown, greyish-orange or medium brown | |
| No | No | Unicuspid | Bicoloured (Bicoloured) | Absent | Greyish-brown, reddish-brown, dark brown or blackish | |

***Pipistrellus aero* Mt GARGUES PIPISTRELLE**

Fr. Pipistrelle du Kenya; Ger. Luftige Zwergfledermaus

Pipistrellus aero Heller, 1912. Smithson. Misc. Coll. 60 (12): 3. Mt Gargues, Matthews Range, Kenya.

Taxonomy Traditionally *Pipistrellus aero*, but subsequently classified as *P. (Pipistrellus) aero* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005). Allen (1917a) mistakenly assumed that *P. aero* was near *P. nanus*. Koopman (1975) suggested that *P. aero* is possibly a subspecies of *P. kuhlii* or *P. deserti*; the relationships between these forms are still uncertain. Specimens from Ethiopia, mentioned by Hayman (1967), are considered to represent *Pipistrellus kuhlii fuscatus* (Hill 1968, Hayman & Hill 1971). Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but sometimes only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (ca. 8–10 mm); FA: 31–34 mm; wings dark without white

hind-border; dorsal pelage dark; dorsal and ventral hairs bicoloured; lower molars nyctalodont; inner upper incisor unicuspid; profile of forehead region of skull moderately concave. A poorly known species. Pelage dense, silky; mid-dorsal hairs ca. 7 mm. Dorsal pelage dark, slightly reddish-brown; hairs blackish-brown at base. Ventral pelage slightly paler; hairs pale reddish-brown with blackish-brown at base. Ears black, relatively short. Tragus length ca. one-third of E; narrow; breadth constant for most of length; breadth much less than length of anterior margin; anterior margin concave; posterior margin smoothly convex; tip rounded. Wings uniformly very dark brown; no white hind-border. Interfemoral membrane very dark brown. Baculum strongly curved with bifurcations both distally and proximally (Figure 139a; Lavrenchenko *et al.* 2004).

Skull medium-sized for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region relatively

| | Anterior upper premolar
(size, visibility above gum, position in toothrow) | FA
(mm) | Miscellaneous | Species |
|--|--|------------|---|------------------------|
| | Medium-sized, conspicuous, within toothrow or slightly displaced | 29–37 | Widespread but disjunct (see map) | <i>P. rueppellii</i> |
| | Medium-sized, visible, slightly displaced linguallly | 25–35 | Sub-Sahara, rainforest and savannas
Day-roosts include furred banana leaves
Rarely any glands on tail | <i>P. nanus</i> |
| | Medium-sized to well-developed, visible, in toothrow or slightly displaced linguallly | 24–29 | Mainly rainforest | <i>P. nanulus</i> |
| | Well-developed, visible, displaced linguallly | 31–33 | NE Libya (Cyrenaica) | <i>P. hanaki</i> |
| | Medium-sized, visible, slightly displaced linguallly | 28–33 | North-west Africa (Maghreb) | <i>P. pipistrellus</i> |
| | Well-developed, visible, uncertain | 34 | Tanzania
Forehead region of skull moderately concave
Only the holotype is known | <i>P. permixtus</i> |
| | Minute, usually not visible, displaced linguallly | 25–34 | North Africa to Equator
Forehead region of skull moderately concave
GLS: 11.7 (10.8–12.4) mm | <i>P. deserti</i> |
| | Minute, hardly visible, usually displaced linguallly | 29–37 | North Africa only
Forehead region of skull moderately to weakly concave
GLS: 13.2 (12.3–13.8) mm | <i>P. kuhlii</i> |
| | Minute, often not visible, displaced linguallly | 31–34 | Kenya, Ethiopia
Forehead region of skull moderately concave | <i>P. aero</i> |
| | Minute, seldom visible, displaced linguallly, sometimes absent | 24–31 | Sub-Saharan savanna, woodland and bushland zones
Forehead region of skull straight to weakly concave | <i>P. rusticus</i> |
| | Medium-sized to minute, usually visible, within toothrow to fully displaced linguallly | 29–38 | Forehead region of skull moderately concave | <i>P. hesperidus</i> |

narrow; rostrum relatively long and broad (Table 25, p. 603). Profile of forehead region (viewed laterally) moderately concave. No occipital helmet. Upper incisors conical, unicuspid. Outer incisor less than half height of inner incisor. Anterior upper premolar present, but minute, displaced linguallly and often not visible above gum. Lower molars nyctalodont (M. D. Carleton pers. comm.). Dental formula: $\frac{2123}{3123} = 34$.

Geographic Variation None recorded.

Similar Species Three other sub-Saharan *Pipistrellus* have lower molars nyctalodont; inner upper incisors unicuspid (Table 27, p. 608):

Pipistrellus rusticus. Dorsal pelage reddish-brown to medium brown. Forearm usually shorter (24–31 mm). Profile of forehead region of skull straight or almost straight. Widespread.

P. deserti. Dorsal pelage pale sepia brown to pale yellowish-brown (sometimes with greenish tint); wings with white hind-border. Algeria to Egypt, West Africa, Sudan, Somalia.

P. hesperidus. Interfemoral membrane paler and more translucent than wing-membranes. Comparatively widespread.

Distribution Endemic to Africa. Known only from the Afromontane–Afroalpine BZ at Mt Gargues, Kenya (Heller 1912) and at three localities in Ethiopia (see below), and from the Somalia–Masai BZ at L. Marsabit and Ngong (Aggundey & Schlitter 1984). Specimens from south of L. Tana, Ethiopia, mentioned by Hayman & Hill (1971) do not seem to represent *P. aero* and this locality is questioned. However, recently acquired specimens (now in ZMMU) from three other localities in Ethiopia do represent this species (Lavrenchenko *et al.* 2004). These Ethiopian localities (not mapped) are the tributary of Beko R. (07° 07'N, 35° 25'E, 1300 m), Godare Forest, Dushi Area, Yamboshi R. (07° 21'N, 35° 13'E, 1200 m) and Chercher Mts, between Hirna and Deder (09° 20'N, 41° 16'E, 2700 m). The distance between these localities, and the differences in altitude, suggest that *P. aero* is probably widely distributed in Ethiopia.

Habitat Heller (1912) reported this species from ‘heavy forest’ (= montane forest) on the summit of Mt Uarguess (= Mt Gargues, Mathews Range, Kenya). The other Kenyan localities are in a vegetation zone described as a mosaic of evergreen bushland and secondary *Acacia* wooded grassland but, at L. Marsabit, there is afromontane vegetation in the area.

*Pipistrellus aereo*

Conservation IUCN Category: Data Deficient.

Pipistrellus anchietae ANCHIETA'S PIPISTRELLE

Fr. Pipistrelle d'Anchieta; Ger. Anchieta's Zwergfledermaus

Pipistrellus anchietae (Seabra, 1900). J. Sci. Math. Phys. Nat. Lisboa, ser. 2, 6: 26, 120. Cahata, Angola.

Taxonomy Originally *Vesperugo anchieta*. The emendation to *anchietae* is justified; *anchietai* is incorrect (Kock 2001a). Traditionally *Pipistrellus anchietae*. Subsequently classified as *P. (Hypsugo) anchietae* by Hill & Harrison (1987) and Koopman (1993) and as *Hypsugo anchietae* by Kearney *et al.* (2002) and Simmons (2005). In contrast, Hoofer & Van Den Bussche (2003) question the placement of *anchietae* in *Hypsugo*. Placed in collective group *Attalepharca* by Menu (1987). Identification of *P. anchietae* using chromosomes and bacula has shown that keys, using tooth shape and height characters (e.g. Meester *et al.* 1986) are problematic (Kearney & Taylor 1997). It is possible that more *P. anchietae* exist in collections, misidentified as *P. kuhlii* (Hill & Carter 1941, Kearney & Taylor 1997). Synonyms: tentatively none. Koopman (1975, 1993) considered *anchietae* a synonym of *Pipistrellus bicolor*, which is the prior name. However, *bicolor* is tentatively treated here as a synonym of *P. tenuipinnis* (see profile of *P. tenuipinnis*). Subspecies: none. Chromosome number (South Africa): 2n = 26; aFN = 32 (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (10–23 mm); FA: 29–34 mm; dorsal pelage brown; dorsal and ventral hairs bicoloured; wings dark with or without white hind-border;

lower molars myotodont; inner upper incisors bicuspid; profile of forehead region of skull weakly concave. Sexes similar. Pelage soft, dense; mid-dorsal hairs ca. 6 mm. Dorsal pelage yellowish-brown, reddish-brown, medium brown or dark brown; hairs with basal two-thirds blackish-brown. Ventral pelage pale brown, cream or white; palest in pelvic region; hairs mostly with basal two-thirds blackish-brown but some all-white hairs in pelvic region. Bare skin on muzzle and around eyes medium or dark brown. Buccal glands have been observed in one ♀. Ears medium-brown, subtriangular with rounded tip. Tragus length ca. half of E; posterior margin smoothly convex with basal lobe; tip rounded. Wing-membranes dark brown or blackish-brown, sometimes without white hind-border, sometimes with very narrow white hind-border. Interfemoral membrane paler (medium or dark brown). Baculum as in Figure 140a, b (Hill & Harrison 1987) (but see Kearney *et al.* 2002 for variation).

Skull medium-small and gracile for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region of medium relative breadth; rostrum of medium relative length but relatively narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave. Rostrum with well-developed lateral depressions just above the infraorbital foramina (J. E. Hill in Rautenbach *et al.* 1985) as in *P. inexpectatus* and some *P. capensis*. No occipital helmet. Inner upper incisor bicuspid. Outer upper incisor minute. Anterior upper premolar minute, not visible above gum, displaced lingually

but canine and posterior premolar not in contact. Lower molars myotodont (Menu 1987). Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation None recorded.

Similar Species One African *Eptesicus* and four other African *Pipistrellus* also have dark wings; bicoloured dorsal hairs; myotodont lower molars; and have (or might have) distributions overlapping that of *P. anchietae* (Table 26, p. 606):

Pipistrellus capensis. Inner upper incisor weakly bicuspid before tooth is worn, then unicuspid. Anterior upper premolar absent. Occipital helmet well developed.

P. somalicus. Hairs faintly bicoloured. Inner upper incisor unicuspid or weakly bicuspid. Anterior upper premolar absent. Widespread south of Sahara.

P. zuluensis. Dorsal hairs bicoloured or tricoloured. Inner upper incisor usually unicuspid. Anterior upper premolar absent.

P. cf. melckorum. Inner upper incisor bicuspid. Anterior upper premolar absent. Skull longer (GLS: 13.7–15.5 mm).

Eptesicus hottentotus. Much larger (FA: 45–54 mm; GLS: 16.9–21.5 mm).

Distribution Endemic to Africa. Mainly found in the Zambezan Woodland BZ, but extends marginally into the South-West Arid BZ in S Angola and into the Coastal Forest Mosaic BZ in South Africa. Recorded from Angola, S DR Congo, Zambia, Zimbabwe and South Africa.

Habitat Found in riverine, coastal and scrub forests as well as bushveld, often in vicinity of open water.

Abundance Rare, but possibly more specimens exist, misidentified as *P. hesperidus*.

Remarks Has been caught while flying over or near water, along dirt roads with thick bush on either side and along dry river beds. One was found roosting in a tree in woodland at the edge of a riverine forest in Zambia (HZM). In KwaZulu–Natal (South Africa), 3 of 3 ♀♀ were reproductively inactive in Apr–May; 1 of 1 was pregnant with two foetuses in Nov (Kearney & Taylor 1997).

Conservation IUCN Category: Least Concern.

Pipistrellus ariel FAIRY PIPISTRELLE

Fr. Pipistrelle ariel; Ger. Elfen-Zwergfledermaus

Pipistrellus ariel Thomas, 1904. Ann. Mag. Nat. Hist., ser. 7, 14: 157. Wadi Alagi, (22°N, 35°E, 610 m), Kassala Province, Sudan.

Taxonomy Traditionally *Pipistrellus ariel*. Subsequently classified as *P. (Hypsugo) ariel* by Hill & Harrison (1987) and Koopman (1993) and as *Hypsugo ariel* by Simmons (2005). The closest ally of this species appears to be the South-West Asian *Pipistrellus bodenheimeri* Harrison, 1960, with which it might be conspecific (Yom-Tov *et al.* 1992). Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but often only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (ca. 9–11 mm); FA: 30–31 mm; dorsal pelage pale; dorsal and ventral hairs bicoloured; wings dark without white hind-border; lower molars myotodont; inner upper incisor unicuspid; profile of

forehead region of skull strongly concave. A poorly known species. Pelage not dense; mid-dorsal hairs 5–6 mm. Dorsal pelage pale pinkish-brown to pale greyish-cream, with underlying colour showing through; hairs blackish-brown at base. Ventral pelage slightly paler; hairs blackish-brown with pale greyish-cream at tip. Ears relatively short; inner margin convex; outer margin concave; tip rounded. Tragus length ca. one-third of E ($n = 1$); maximum breadth only a little less than length of anterior margin; anterior margin straight; posterior margin smoothly convex with distinct lobule at base; tip rounded (Figure 136d). Wings pale brown; no white hind-border. Interfemoral membrane pale brown; postcalcarea lobe very narrow; tail projecting slightly beyond edge of membrane. Penis relatively short. Baculum as in Figure 140c (Makin & Harrison 1988).

Skull small and gracile for an African *Pipistrellus*. Braincase of medium relative height and relatively narrow; interorbital region relatively narrow; rostrum flattened, of medium relative length and relatively narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) strongly concave. No occipital helmet. Inner upper incisor unicuspid. Outer upper incisor about two-thirds length of inner upper incisor. Anterior upper premolar minute, sometimes not visible above gum, displaced lingually; canine and posterior upper premolar in contact. Lower molars myotodont. Dental formula: $\frac{2123}{3123} = 34$.

Geographic Variation None recorded.

Similar Species In Sudan and S Egypt, three other dark-winged *Pipistrellus* and one *Eptesicus* have lower molars myotodont; dorsal hairs bicoloured (Table 26, p. 606):

Pipistrellus capensis. Skull apparently larger (GLS: 12.0–15.4 mm; C–M³: 3.6–5.6 mm). Profile of forehead region of skull almost straight. Inner upper incisor weakly bicuspid before wearing. Anterior upper premolar absent. Widespread south of Sahara.

P. somalicus. Pelage only faintly bicoloured. Ventral pelage brown. Profile of forehead region of skull weakly concave. Outer upper incisor hardly higher than cingulum of inner incisor. Anterior upper premolar absent. More widely distributed (see Map).

P. guineensis. Ventral pelage dark rusty-brown. Inner upper incisor bicuspid. Anterior upper premolar absent.

Eptesicus bottae. Much larger (FA: 38–47 mm; GLS: 15.3–18.0 mm). Anterior upper premolar always absent.

Distribution In Africa, known with certainty only from two localities in Sudan (Koopman 1975, Qumsiyeh 1985), one in the Sahara Arid BZ and the other in the Sahel Savanna BZ. There is an unconfirmed sight record from Bir Kansisrob, Egypt (Sanborn & Hoogstraal 1955), which is not mapped. An Egyptian record mentioned by Gaisler *et al.* (1972) was found to represent *P. deserti* (Hill & Harrison 1987, Kock 1999). Extralimittally: Israel (Makin & Harrison 1988) and Jordan (Qumsiyeh *et al.* 1992).

Habitat The type locality is a valley (wadi) at ca. 670 m, in an area of gravel and stony desert incised by wadis that are dry except after heavy rain. The most southern record is from Rahad in Sudan

Pipistrellus ariel

(12° 45' N, 30° 40' E), in *Acacia* wooded grassland and deciduous bushland.

Abundance Apparently extremely rare (Harrison & Bates 1991).

Remarks Nothing else is known about this species.

Conservation IUCN Category: Data Deficient.

Pipistrellus brunneus DARK-BROWN PIPISTRELLE

Fr. Pipistrelle brune; Ger. Dunkelbraune Zwergfledermaus

Pipistrellus brunneus (Thomas, 1880). Ann. Mag. Nat. Hist., ser. 5, 6: 165. Calabar, SE Nigeria.

Taxonomy Originally *Vesperugo* (*Vesperus*) *brunneus*. Traditionally *Eptesicus brunneus*. Subsequently classified as *P. (Neoromicia) brunneus* by Hill & Harrison (1987), *Nycterikaupius brunneus* by Menu (1987), *E. (Neoromicia) brunneus* by Koopman (1993), *P. (Neoromicia) brunneus* by Koopman (1994) and *Neoromicia brunneus* by Simmons (2005). Hoofer & Van Den Bussche (2003) allocated *brunneus* together with *rendalli* and *nanus* to a yet unnamed genus. Synonyms: none. Chromosome number (Cameroon): $2n = 36$; $aFN = 50$ (McBee *et al.* 1987). The karyotype does not fit the general *Eptesicus*-pattern, which is very conservative, but agrees with the more variable '*Pipistrellus*'-pattern, supporting an arrangement within *Neoromicia* (Hill & Harrison 1987, McBee *et al.* 1987).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper cheekteeth, five lower cheekteeth and two upper incisors on each side; ears separated and short (9–15 mm); FA: 33–38 mm; wings blackish-brown without white hind-border; dorsal pelage dark; dorsal hairs unicoloured, ventral hairs bicoloured; lower molars myotodont; inner upper incisor unicuspid; profile of forehead region of skull weakly concave; posterior margin of tragus sharply angular. Sexes similar. Pelage dense, soft. Dorsal pelage varying from medium brown, reddish-brown to dark chocolate brown; hairs unicoloured. Ventral pelage shorter and paler; hairs blackish-brown with pale greyish-brown tips or medium-brown tips. Buccal glands sometimes very prominent. Ears blackish, subtriangular with rounded tip. Tragus length ca. 40% of E and broad; anterior margin short and straight; posterior margin with sharp angle giving tragus a diagonally truncated appearance (Figure 136a). Thumb comparatively long and slender for a *Pipistrellus*. Wing-membranes blackish-brown without white hind-border. Because wing colour was not mentioned in the type description, and because the wings of the holotype were bleached by preservative, *P. brunneus* was grouped with the pale-winged species (*P. rendalli*, *P. tenuipinnis*) (e.g. Rosevear 1965), but Koopman (1965) and De Vree (1971) showed that it is dark-winged. Bacular morphology: no information.

Skull large and robust for an African *Pipistrellus*. Braincase domed, relatively high but of medium relative breadth; interorbital region relatively narrow; rostrum of medium relative length and breadth (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave. Sagittal and lambdoid crests very weakly developed; no occipital helmet. Inner upper incisor unicuspid (without accessory cusp at posterior base of tooth (cf. *P. rendalli*)). Outer upper incisor ca. one-quarter to one-third height of inner incisor (usually reaching only slightly above cingulum of inner incisor). Anterior upper premolar absent. Lower molars myotodont. Dental formula: usually $2^{113}/_{3123} = 32$.

Geographic Variation Apparently none.

Similar Species Five other African *Pipistrellus* have dark wings; unicoloured dorsal hairs; myotodont lower molars (Table 26, p. 606):

Pipistrellus grandidieri. Dorsal pelage pale brown. Ventral hairs unicoloured, yellowish. Posterior margin of tragus smoothly convex for most of its length. Inner upper incisor bicuspid. Anterior upper premolar sometimes present although not always visible above gum.
P. crassulus crassulus. Ventral pelage dark brown or reddish-brown; hairs unicoloured. Posterior margin of tragus smoothly convex for most of its length. Inner upper incisor bicuspid. Anterior upper premolar present although not always visible above gum.
P. crassulus bellieri. Posterior margin of tragus smoothly convex for most of its length. Inner upper incisor bicuspid. Anterior upper premolar present and visible above gum.
P. musciculus. Much smaller (FA: 23–26 mm; GLS: 10.3–11.4 mm). Posterior margin of tragus smoothly convex for most of its length. Inner upper incisor bicuspid.

Distribution Endemic to Africa. Recorded mainly from the Rainforest BZ (Western and West Central regions), but also recorded marginally from the Rainforest–Savanna Mosaic and, in Côte d'Ivoire, from the Guinea Savanna BZ. There are ca. 22 records from Sierra Leone, Liberia, Côte d'Ivoire, Ghana, SE Nigeria, Cameroon, Equatorial Guinea, Gabon (Cape Esterias; V. Van Cakenberghe pers. comm.) and DR Congo. Specimens from Nko, Nigeria in BMNH, published as *Eptesicus brunneus* by Sanderson (1939), Rosevear (1965), Hayman & Hill (1971) and Happold (1987), represent *P. rendalli* (De Vree 1973a, Hill & Harrison 1987). The only known specimen from the central Congo Basin (Lukolela, AMNH) was identified as *P. brunneus* by Koopman (1965). This record appears to be rather isolated and the specimen should be re-examined.

*Pipistrellus brunneus*

Habitat Apparently one of the most specialized rainforest vespertilionids, known almost exclusively from localities in undisturbed to slightly disturbed lowland rainforests. Within the Rainforest BZ, has been recorded mainly from both evergreen and semi-deciduous lowland rainforests, but also from swamp forest, and mangroves. Two other records are from riverine forest within the Rainforest–Savanna Mosaic (near Fintona, Sierra Leone) and from a relict forest within the Guinea Savanna BZ (Comoé N. P., Côte d'Ivoire). Although mostly found at low altitudes, a record from Bake River bridge, Cameroon, is located at ca. 1470 m in sub-montane forest.

Abundance Localized but apparently not rare in suitable habitat.

Adaptations No information.

Foraging and Food No detailed information. Presumably forages by slow-hawking (as in other *Pipistrellus*). In Tai N. P. and Comoé N. P., Côte d'Ivoire, mostly caught in harp-traps or mist-nets near small forest creeks and in elevated mist-nets 0–25 m above ground, in tree-fall gaps within the forest. Individuals were caught at a median height of 9 (1–21) m ($n = 9$) (J. Fahr unpubl.). Diet not known.

Echolocation No information.

Social and Reproductive Behaviour No information.

Reproduction and Population Structure Litter-size: one ($n = 1$). Reproductive chronology not known (data inconclusive). At 05° 50' N (Tai N. P., Côte d'Ivoire), 4 of 5 ♂♂ had scrotal testes between Feb and Mar; 1 of 1 ♀ was pregnant in late Sep; 1 of 1 was lactating in late Feb and one was lactating in early Mar, and 1 of 1 was neither lactating nor pregnant in late Aug (Lim & Van Coeverden de Groot 1997, J. Fahr unpubl.). At 05° 22' N (Banco N. P., Côte d'Ivoire) 1 of 2 ♀♀ was pregnant, the other was neither lactating nor palpably pregnant, and 2 of 2 ♂♂ had scrotal testes in mid-Sep. At 09° 40' N (near Fintonia, Sierra Leone), two lactating ♀♀ were collected in late Apr (total number of captured ♀♀ not known)

(USNM). In a sample of eight bats from Tai N. P., the ratio of ♂♂ to ♀♀ was 1 : 1.7, and in 15 museum specimens from West Africa, the ratio was 1 : 1.5.

Predators, Parasites and Diseases Ectoparasites include a bat-fly *Basilia echinata* (Diptera: Nycteribiidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Near Threatened.

Apparently rare and only known from ca. 22 localities, mostly in the rainforest zone that is already, and to a large extent, degraded or destroyed. Major threats: loss and degradation of habitat as result of deforestation and agriculture. Population trend inferred to be declining.

Pipistrellus capensis CAPE PIPISTRELLE

Fr. Pipistrelle du Cap; Ger. Kap-Zwergfledermaus

Pipistrellus capensis (A. Smith, 1829). Zool. J. 4: 435. Grahamstown, Cape Province, South Africa.

Taxonomy Originally *Vespertilio capensis*. Traditionally *Eptesicus capensis*. Subsequently classified as *P. (Neoromicia) capensis* by Hill & Harrison (1987), *Nycterikaupius capensis* by Menu (1987), *E. (Neoromicia) capensis* by Koopman (1993), *P. (Neoromicia) capensis* by Koopman (1994) and *Neoromicia capensis* by Volleth *et al.* (2001), Kearney *et al.* (2002) and Simmons (2005). In contrast, Hooper & Van Den Bussche (2003), pending further study, restrict *Neoromicia* to *N. somalicus*. Synonyms: *damarensis*, *garambae*, *gracilior*, *nkatiensis*, *notius* and probably *melckorum* Roberts, 1919 (but not all material, see profile of *P. cf. melckorum*). Subspecies: none recognized here (see Geographic Variation). *Pipistrellus capensis* has long been a taxonomic problem. It has a very wide geographic range and shows considerable variation in colour and size. Whether this variation is indicative of different

species or races, or is ecologically induced, remains to be answered. Chromosome number (Zimbabwe, South Africa): $2n = 32$; $aFN = 50$ (Volleth *et al.* 2001, Kearney *et al.* 2002).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; usually with four upper cheekteeth (sometimes five but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (8–15 mm); FA: 28–38 mm; wings dark, occasionally with narrow white hind-border; dorsal pelage pale to dark; dorsal and ventral hairs bicoloured; lower molars myotodont; inner upper incisor weakly bicuspid when not worn; profile of forehead region of skull straight to weakly concave. Sexes alike in colour; in

some localities, ♀♀ on average larger than ♂♂ e.g. in South Africa, FA (♀♀): 34.9 (32–38) mm, $n = 24$, FA (♂♂): 32.1 (30–35) mm, $n = 16$; GLS (♀♀): 14.1 (12.8–15.0) mm, $n = 24$, GLS (♂♂): 13.3 (12.2–14.5) mm, $n = 16$. Pelage soft, dense; mid-dorsal hairs 5–6 mm. Dorsal pelage very variable – pale yellowish-brown, pale greyish-brown, reddish-brown, and all shades of brown (from pale to dark brown); hairs with basal two-thirds dark brown or black. Some individuals paler around eyes and mouth; others with white-tipped hairs scattered through dorsal pelage. Ventral pelage white, whitish, cream or buff; hairs mostly bicoloured with basal three-fifths brownish-black or black, but some all-white hairs in pelvic region and adjacent to flight-membranes. Ears subtriangular with rounded tip. Tragus length ca. 45% of E; widest at middle or a little below; posterior margin smoothly convex for most of its length; tip rounded (Figure 136e). Wing-membranes yellowish-brown, greyish-brown or blackish-brown, occasionally with narrow white hind-border; dorsal pelage and membrane colours similar. Interfemoral membrane paler, more translucent, sometimes with yellowish border; transverse lines dark (cf. *Cistugo*). Tail 65–66% of HB (cf. *Cistugo* spp.). Baculum as in Figure 141a (Harrison & Hill 1987); variation in Kearney *et al.* (2002).

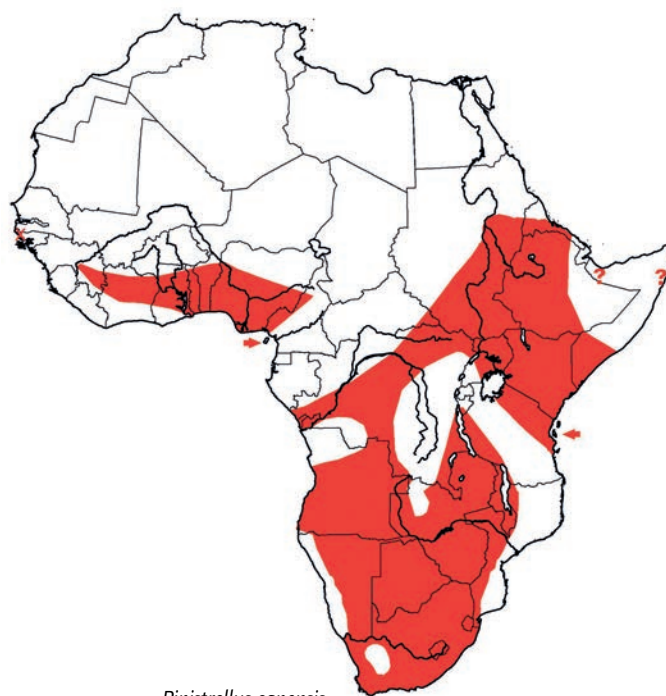

Skull comparatively large and robust for a *Pipistrellus*. Braincase relatively low but of medium relative breadth; interorbital region relatively narrow; rostrum of medium relative length and breadth (Table 25, p. 603). Rostrum sometimes with well-developed lateral depressions just above the infraorbital foramina as in *P. anchietae* and *P. inexpectatus*. Profile of forehead region (viewed laterally) straight to weakly concave. Occipital helmet (formed when the backward-pointing lambdoid crest and the posterior end of the sagittal crest are well developed) usually present, but specimens with little tooth-wear do not always have a helmet. With experience, the straight forehead and occipital helmet (if present) can be felt (without extracting skull) by stroking the head from rostrum to back of neck. Inner upper incisor almost always appears unicuspid, but is weakly bicuspid in specimens with very little tooth-wear. Outer upper incisor less than half height of inner incisor but reaching above its cingulum. Anterior upper premolar usually absent: reported present but minute, on one or both sides, in some specimens in northern part of distribution, but this condition is extremely unusual. Lower molars myotodont. Dental formula: usually $2^{113}/_{3123} = 32$.

Geographic Variation Koopman (1994) lists seven subspecies, of which one, *matroka* from Madagascar, is no longer included in *P. capensis* (Peterson *et al.* 1995), and another, *grandidieri*, is now considered a distinct species:

- P. c. capensis*: Eastern Cape Province.
- P. c. damarensis*: Angola and Zambia to Namibia and Botswana.
- P. c. garambae*: S Sudan and NE DR Congo.
- P. c. gracilior*: Mozambique to KwaZulu–Natal, South Africa.
- P. c. notius*: Western Cape Province.

Simmons (2005) also lists *P. c. nkatiensis* Roberts 1932 as a subspecies, without giving its distribution. Koopman (1994) points out that most West African populations have not been allocated to subspecies.

Similar Species One African *Eptesicus* and eight other African *Pipistrellus* also have dark wings; bicoloured dorsal hairs; myotodont

Pipistrellus capensis

lower molars; and have (or might have) distributions overlapping that of *P. capensis* (Table 26, p. 606):

- Pipistrellus ariel*. Skull apparently smaller (GLS: 11.1, 11.3 mm: C–M³: 3.8, 4.1 mm, $n = 2$). Profile of forehead region of skull strongly concave. Inner upper incisor always unicuspid; anterior upper premolar present but minute and sometimes not visible. Sahara Arid and Sahel Savanna BZs of Sudan and perhaps Egypt.
- P. cf. melckorum*. Forearm on average longer (37.1 [36–39] mm in karyotypically confirmed material, 35.3 [32–38] mm in non-confirmed material). Tail on average longer (39.6 [35–44] mm), $n = 5$). Inner upper incisor always unicuspid; molars more massive. Zambezi Woodland BZ.
- P. somalicus*. Hairs only inconspicuously bicoloured. Ventral pelage brown. Dorsal hairs often longer (5–8 mm). FA not >32 mm. No sagittal crest. In older animals with some tooth-wear, an occipital helmet is present but comparatively weakly developed. Profile of forehead region of skull weakly concave.
- P. zuluensis*. Dorsal hairs bicoloured or tricoloured. Ventral pelage pale greyish-brown. Braincase more inflated and globular; rostrum shorter and narrower; profile of forehead region weakly to moderately concave. Occipital helmet absent, therefore braincase smoothly rounded posteriorly. With experience, the globular braincase, concave forehead and lack of helmet can be felt without extracting the skull. Outer upper incisor ca. half height of inner incisor.
- P. anchietae*. Inner upper incisor bicuspid. Anterior upper premolar present but not visible above gum. No occipital helmet.
- P. inexpectatus*. Inner upper incisor bicuspid. Anterior upper premolar present although not visible above gum. Ventral pelage reddish-cream.
- P. guineensis*. Ventral pelage dark rusty-brown. Inner upper incisor bicuspid. Skull shorter, GLS: 10.7–11.8 mm.
- P. eisentrauti*. Inner upper incisor bicuspid. Anterior upper premolar usually present.

Eptesicus hottentotus. Much larger (FA: 45–54 mm; GLS: 16.9–21.5 mm).

Distribution Endemic to Africa. Recorded in at least some parts of all biotic zones south of the Sahara, from Guinea-Bissau to Ethiopia and southwards to South Africa; also Bioko I. and Zanzibar I. Not recorded from Western Region of Rainforest BZ and from much of West Central region, and probably absent from the arid Horn of Africa and most of the Namib Desert. Two unconfirmed reports from E Somalia are plotted as question marks. The gap in NE Angola, and the gap from C DR Congo through Tanzania to Mozambique, probably reflect insufficient sampling. Map based on data from V. Van Cakenbergh (pers. comm.).

Habitat Recorded in most vegetation zones south of Sahara, except large deserts and some coastal habitats. Often associated with human settlements.

Abundance Common; their success being assisted in more recent history by their use of man-made roosts.

Adaptations Aspect ratio low; wing-loading very low (M. Happold pers. comm.). Flight can be fairly slow and fluttering or sometimes faster; moderately manoeuvrable; turns by banking (minimum radius just under 50 cm) and only rarely by stalling-and-twisting; individuals could fly across a 1×1×1 m enclosure but could not fly more than one complete circuit/flight (8 bats, 10 flights each; M. Happold pers. comm.). Can take off from ground; cannot hover. Climbs and scuttles moderately well. Roosts by day in restricted cavities: e.g. under bark of trees, among leaves of aloes, in cracks or holes in plants and rocks, in ceilings, under roofs (including between sheets of corrugated iron) and in walls of buildings (Rosevear 1965, Smithers 1983). Sometimes roosts with *Scotophilus dinganii*. In South Africa, frequently active during winter and apparently does not enter prolonged periods of torpor (van der Merwe 1994a) although becomes torpid during day (even at 21–24 °C; Happold & Happold 1988) and sometimes remains torpid for a few days. Predicted mean maximum urine concentration comparatively high (4427 mOsmol/kg); captive bats, fed winged termites, sometimes did not drink for up to 3.5 days (Happold & Happold 1988). There are several glands on the face, above the eye, in the corner of the mouth, on either side of the muzzle and under the chin. In South Africa, these glands change seasonally, becoming more conspicuous and in some cases excreting a clear fluid, in Mar and Apr, which is the same time as mating occurs.

Foraging and Food Forages by slow-hawking in moderately clutter-free spaces including between trunks of trees, around and over canopies (but not at high altitudes) and clearings fairly close to vegetation; sometimes forages within a metre of canopy foliage (M. Happold pers. comm.). Attracted to concentrations of insects around vegetation, over water, over termite mounds when winged termites are emerging, and around lights. In such situations, flight characterized by swerving and jinking and some direct pursuits. Emerges at dusk; has several bouts of foraging per night, with peak activity at dusk and just before dawn. Activity reduced by moonlight, probably to reduce risk of predation. Tends not to fly in heavy rain and strong wind. Faeces, in wet/dry seasons in Zimbabwe, contained Coleoptera

(68/26%), Lepidoptera (18.5/7.4%), Hemiptera (6/0%), Diptera (6/5.4%) and Trichoptera (0/45%) (n = 40/13 bats) (Fenton *et al.* 1977, Fenton & Thomas 1980). Fenton & Thomas (1980) noted that *P. capensis* and *Nycticeinops schlieffeni* took more caddis-flies (Trichoptera) than other bats in the study area, and suggested this was related to their early emergence and canopy-associated foraging behaviour.

Echolocation Search-phase call-shape (Malawi) steep FM/QCF (QCF 'heel' sometimes missing, sometimes replaced by short shallow FM sweep) (Figure 118d). Intensity high; start-frequency 65–84 kHz; end-frequency 38–44 kHz (ten bats, 332 calls; M. Happold pers. comm.). In Zimbabwe, end-frequency 35 kHz (five bats; Fenton & Bell 1981). In South Africa, end-frequency 35–37 kHz (four bats in flight cage, 20 light-tagged; Aldridge & Rautenbach 1987, one bat in room, one bat in open; Taylor 1999a). In contrast, peak-frequency is similar in all three localities: 38–44 kHz (usually 39–41 kHz) (Malawi), 40 kHz (Zimbabwe), 38–40 kHz (South Africa). Call-duration: 3.5–8 ms.

Social and Reproductive Behaviour Earlier accounts indicated that this species roosts singly, which appears to be the case in natural roosts. Now, however, often found in buildings, roosting in mixed-sex groups of ca. 20 individuals.

Reproduction and Population Structure Litter-size (southern Africa, based on embryo counts): usually two, often three, occasionally one or four (van der Merwe 1994a). At 24° S (former Transvaal, South Africa), the reproductive chronology is usually restricted seasonal monoestry with spermatogenesis peaking in Mar–May; the first copulations in late Mar to early Apr; sperm storage by the ♀♀ and also additional copulations until ovulation and fertilization occur in second half of Aug; and parturition in late Oct to early Nov after gestation of ca. 12 weeks (van der Merwe 1994a). Rarely, pregnant ♀♀ have been found in Mar (Lynch 1989).

A ♂ and ♀ born in captivity were born hairless with eyes closed. Eyes started opening on Day 8 and were fully open by Day 11; bodies furred by Day 12. Born with forearms 36.0% (♀) and 36.8% (♂) of the adult length; forearms reached 87.5% (♂) and 85.8% (♀) of adult length by Day 38.

Predators, Parasites and Diseases Predators include Barn Owls *Tyto alba* (Dean 1975, Avery 1992), Pied Crows *Corvus albus* (Smithers 1983) and probably Bat Hawks *Macheiramphus alcinus* (Fenton *et al.* 1977). One of these bats was found in a spider's (*Nephila* sp.) web in Serengeti N. P., Tanzania (Verschuren 1965b). Ectoparasites include a bed-bug *Cacodmus villosus* (Hemiptera: Cimicidae); fleas *Echidnophaga gallinacea* (Siphonaptera: Pulicidae), *Araeopsylla scitula*, *Damfia grahamsi*, *Ischnopsylla emmina* (Siphonaptera: Ischnopsyllidae); bat-flies *Nycteribia schmidli*, *Basilia robusta* (Diptera: Nycteribiidae); ticks *Carios vespertilionis*, *C. confusus* (Acari: Argasidae); and a mite *Acanthophthirus capensis* (Acari: Myobiidae) (Anciaux de Faveaux 1984, Beaucournu & Kock 1996).

Conservation IUCN Category: Least Concern.

Teresa Kearney

Pipistrellus crassulus BROAD-HEADED PIPISTRELLE

Fr. Pipistrelle à grosse tête; Ger. Breitköpfige Zwergfledermaus

Pipistrellus crassulus Thomas, 1904. Ann. Mag. Nat. Hist., ser. 7, 13: 206. Efulen [= Efulan], SW Cameroon.

Taxonomy Traditionally *Pipistrellus crassulus*. Subsequently classified as *P. (Pipistrellus) crassulus* by Hill & Harrison (1987) and Koopman (1993) and as *P. (Vansonia) crassulus* by Koopman (1994). Placed in collective group *Attalepharca* by Menu (1987), in *Hypsugo* by Heller *et al.* (1994), Volleth *et al.* (2001) and Simmons (2005), and in *Nycticeinops* by Hooper & Van Den Bussche (2003; as *eisentrauti*). Synonyms: possibly *bellieri*. This taxon was described as a subspecies of *P. eisentrauti* by De Vree (1972), then transferred to *P. crassulus* by Heller *et al.* (1994) (but see Koopman 1993, Koopman *et al.* 1995). It might be a valid subspecies (and is treated as such here), but it is probably a distinct species. For this reason, the descriptions, distributions, habitats and biology of the two taxa are given separately in each section of this profile. Chromosome number (*P. c. crassulus*, DR Congo): 2n = 30; aFN = 56 (Volleth *et al.* 2001). Chromosome number (*P. c. bellieri*): not known.

Description *Pipistrellus c. crassulus* is a very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but often only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (9–12 mm); FA: 28–32 mm; wings blackish-brown without white hind-border; dorsal and ventral hairs unicoloured; lower molars myotodont; inner upper incisor bicuspid; skull conspicuously broad and flattened, dorsal profile almost straight. Sexes similar. Pelage soft, dense; mid-dorsal hairs ca. 4–5 mm. Dorsal pelage dark brown or reddish-brown; hairs unicoloured. Ventral pelage same as dorsal; hairs unicoloured. Throat same colour as rest of ventral pelage. Ears blackish, rounded; 29–39% of FA (cf. *P. c. bellieri*). Tragus length ca. 35–45% of E; broadest at base of anterior margin; anterior margin straight, posterior margin smoothly convex with small basal lobe. Tail relatively longer than in *P. c. bellieri* (63 [57–67]% of HB). Wing- and interfemoral membranes dark blackish-brown, no white hind-border. Penis unusually long for a *Pipistrellus*. Baculum very long and slender, tip not bifid but simple, very small basal lobes in line with the extended bacular shaft in the vertical plane (Figure 140d; Hill & Harrison 1987); for variation see Heller *et al.* (1994).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase relatively low, broad and rounded; interorbital region relatively broad; rostrum low, of medium relative length but relatively broad (Table 25, p. 603). Profile of forehead region (viewed laterally) almost straight to weakly concave. Zygomatic arches slender (cf. *P. eisentrauti*). Sagittal and lambdoid crests weakly

developed; no occipital helmet. Inner upper incisor deeply bicuspid, very broad and robust. Outer upper incisor unicuspid, slender, ca. one-third to half height of inner incisor (cf. *P. c. bellieri*). Anterior upper premolar present but either not visible or only barely visible above gum, displaced lingually in recess between canine and posterior premolar, which are usually in contact or almost so. M³–M³: 5.8 (5.6–5.9) mm (cf. *P. c. bellieri*). Lower incisors trifold (not bifid as stated by Thomas 1904b and Aellen 1959). Lower molars myotodont. Dental formula: $^{2123}/_{3123} = 34$.

Pipistrellus c. bellieri is a very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (usually all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (E: 11–13 mm); FA: 28–33 mm; wings dark without white hind-border; dorsal pelage medium to dark brown; dorsal hairs unicoloured, ventral hairs bicoloured; lower molars myotodont; inner upper incisor bicuspid; profile of forehead region of skull straight to weakly concave. Sexes similar. Pelage mid-dorsal hairs ca. 3–4 mm. Dorsal pelage medium to dark (chocolate) brown; hairs unicoloured. Ventral pelage various shades of pale brown (including pale fawn, pale greyish-fawn); hairs bicoloured (*contra* De Vree 1972, Heller *et al.* 1994), bases medium to dark brown with pale tips. Colour of throat variable but usually paler and contrasting with rest of ventral pelage. Ears dark brown, broadly rounded, 41 (35–46)% of FA (cf. *P. c. crassulus*). Tragus length ca. 43–47% of E; broadest at mid-point; anterior margin straight or slightly convex; posterior margin smoothly convex with small basal lobe; tip rounded. Wing- and interfemoral membranes dark brown; wings without white hind-border. Tail relatively shorter than in *P. c. crassulus* (56 [52–65]% of HB). Penis unusually long for a *Pipistrellus*; dark grey with whitish tip and long, dark hairs. Bacular morphology not known.

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase relatively high, rounded and broad; interorbital region relatively broad; rostrum of medium relative length but relatively broad (Table 25, p. 603). Rostrum comparatively larger and higher than in *P. c. crassulus*. Forehead elevated, inflated and profile (viewed laterally) is weakly concave to straight (Figure 137d). Sagittal and lambdoid crests weakly developed forming a weak occipital helmet. Inner upper incisor bicuspid. Outer upper incisor unicuspid, ca. half to two-thirds height of inner incisor. Anterior upper premolar medium-sized to small (but larger than in *P. c. crassulus*), visible above gum, displaced lingually but canine and posterior premolar usually

separated. M^3-M^3 : 6.1 (5.8–6.3) mm (cf. *P. c. crassulus*). Lower molars myotodont. Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation No subspecies are recognized by Koopman (1994) and Simmons (2005). However, *P. crassulus* contains two populations that are disjunct and sufficiently different in several characters and morphometrically to suggest that they represent distinct species. Pending confirmation of this, they are treated here as subspecies. For diagnostic characters, see Description.

P. c. crassulus: Cameroon, Congo, DR Congo, Sudan, Uganda, Kenya, Angola.

P. c. bellieri: Guinea, Liberia, Côte d'Ivoire.

Similar Species Three other African *Pipistrellus* have dark wings; unicoloured dorsal hairs; myotodont lower molars (Table 26, p. 606):

Pipistrellus grandidieri. Larger (FA: 33–38 mm; GLS: 14.2 [13.8–14.7] mm).

P. musculus. Smaller (FA: 23–26 mm; GLS: 10.3–11.4 mm). Ventral pelage dark umber brown; hairs unicoloured. Anterior upper premolar minute, often not visible.

P. brunneus. Ventral pelage paler, greyish-brown to medium brown; hairs bicoloured. Posterior margin of tragus angular so tragus appears truncated (Figure 136f). Inner upper incisor unicuspid; anterior upper premolar absent.

Distribution Endemic to Africa. Apparently restricted to the Rainforest BZ (Western, West Central, South Central and East Central regions), the adjacent Rainforest–Savanna Mosaic and the Afromontane–Afroalpine BZ. *Pipistrellus c. crassulus* is known from 11 localities in SW Cameroon, Congo (Majumba; MNHN, V. Van Cakenberghe pers. comm.), DR Congo, S Sudan, Uganda, W Kenya and NW Angola. Rosevear (1953) and Rahm (1966) listed this

species for the Cross R. region, Nigeria, but without specific locality or reference to specimens. A doubtful record from Niokolo-Koba N. P., Senegal (Verschuren 1986) needs confirmation and is not mapped here. *Pipistrellus c. bellieri* is known from only seven localities (within 54,000 km²) in the Rainforest BZ and Northern Rainforest–Savanna Mosaic of Guinea, Liberia and Côte d'Ivoire (Roche 1971 [as *P. nanulus*], De Vree 1972, Koopman 1989 [as *P. eisentrauti bellieri*], Lim & Van Coeverden de Groot 1997 [as *P. eisentrauti*], Hoofer & Van Den Bussche 2003 [as *Hypsugo eisentrauti*], J. Fahr unpubl.).

Habitat *Pipistrellus c. crassulus* has been recorded from lowland rainforest, swamp forest, coastal forest and montane forest, and from rainforest in the Rainforest–Savanna Mosaic such as Budongo, Bwamba and Sango Bay Forests in Uganda (LACM, ROM), and Kakamega and Rondo Forests in W Kenya (CM, ROM) (localities from V. Van Cakenberghe pers. comm.). Altitude of known localities 300–1600 m; majority of records between 800–1600 m. *Pipistrellus c. bellieri* is known only from rainforests between 70–600 m.

Abundance No detailed information. Seems to be rather localized but not uncommon in suitable habitat. In Tâi N. P. (Côte d'Ivoire), *P. c. bellieri* was the most frequently caught pipistrelle (J. Fahr unpubl.).

Adaptations One of the few African pipistrelles adapted for foraging in cluttered habitats (see below).

Foraging and Food Forages by slow-hawking, in cluttered habitats such as the understorey of forests. In Tâi N. P., 17 individuals were caught at heights of 1.5–3.4 m in mist-nets set 0–25 m above ground or in harp-traps set across or near small forest creeks. One was caught 20 m above ground in an elevated mist-net set in a tree-fall gap (J. Fahr unpubl.). According to these data, this bat seems to forage mostly in the understorey of the forest and along creeks. Diet not known.

Social and Reproductive Behaviour No information.

Reproduction and Population Structure Litter-size: one ($n = 7$). Reproductive chronology not known (data inconclusive). At 05° 50' N (Tâi N. P., Côte d'Ivoire), 6 of 7 ♀♀ were pregnant and 1 was lactating between late Feb and late Mar, 4 of 4 ♀♀ were nulliparous between late Aug and late Sep, and 1 of 1 ♀ was pregnant in early Oct; 4 of 5 ♂♂ had scrotal testes between late Feb and late Mar and 1 of 1 ♂ had scrotal testes in late Aug (no data for other months) (J. Fahr unpubl.). At 06° 56' N (Mt Peko N. P., Côte d'Ivoire), 1 of 2 ♂♂ had scrotal testes (4×2 mm) and the other had abdominal testes (2×1 mm) in Feb (ROM, Lim & Van Coeverden de Groot 1997). In a sample of 18 bats from Tâi N. P., the ratio of ♂♂ to ♀♀ was 1 : 2.

Predators, Parasites and Diseases Ectoparasites include a mite *Adentocarpus pipistrelli* (Acari: Chirodiscidae) on *P. c. crassulus* (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

The current assessment is based on a monotypic species. If the western population (*P. c. bellieri*) should be confirmed as a separate species, its restricted distribution within the already highly fragmented

and degraded rainforest region of Guinea, Liberia and Côte d'Ivoire would call for concern. The area of occupancy appears to be very small and the population trend can be inferred to be declining due to past and ongoing loss of habitat. Pending the taxonomic status of the species, a ranking as Vulnerable is proposed.

Pipistrellus deserti DESERT PIPISTRELLE

Fr. Pipistrelle du désert; Ger. Wüsten-Zwergfledermaus

Pipistrellus deserti Thomas, 1902. Proc. Zool. Soc. Lond. 2: 4. Mursuk [= Murzuq], Tripoli, Libya.

Taxonomy Traditionally *Pipistrellus deserti* (= *aegyptius*). Subsequently classified in the subgenus *Pipistrellus* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005). Qumsiyeh (1985) suggested that *aegyptius* was the senior synonym of *P. deserti* and many authors, including Koopman (1993, 1994), used this name. However, Kock (1999) showed that *Vespertilio pipistrellus* var. *aegyptius* Fischer, 1829 should be considered a '*nomen dubium*', and he reinstated the name *Pipistrellus deserti*. Koopman (1975) indicated that the closely related *P. aero* Heller, 1912 might be conspecific with *deserti*, or that both *aero* and *deserti* might be dwarf forms of *P. kuhlii*. Molecular data suggest that *deserti* is probably a subspecies of *P. kuhlii* although both forms differ in size (P. Benda & M. Ruedi unpubl.) but, pending confirmation from further studies, it is retained here as a distinct species. Synonyms: probably *minuta* Loche, 1867 (which is considered a synonym of *P. kuhlii* by Simmons 2005 and a '*nomen dubium*' by Kowalski & Rzebik-Kowalska 1991) according to the rather uncertain description details given by Loche (1867). Subspecies: none currently recognized. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but usually only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (7–13 mm); FA: 25–34 mm; dorsal pelage pale; dorsal and ventral hairs bicoloured; wings dark with white hind-border; lower molars nyctalodont; inner upper incisor unicuspid; forehead

region of skull moderately concave; outer upper incisor very small. A poorly known species. Sexes apparently similar in colour; ♀♀ on average slightly larger than ♂♂ in some body dimensions. Pelage texture and length: no information. Dorsal pelage varying from pale sepia brown (= olive-brown) to pale yellowish-brown, sometimes with greenish tint; hairs darker to almost black at base. Ventral pelage greyish or creamy-grey; hairs with dark grey at base. Ears pale buff, translucent, relatively short. Tragus length probably just under half of E, but very variable in preserved material; sickle-shaped; breadth constant for most of length; maximum breadth less than half the length of anterior margin; anterior margin concave (cf. *P. savii*); posterior margin smoothly convex; tip rounded. Wings dark brown with distinct white hind-border. Interfemoral membrane dark brown. Penis short. Baculum thin and long, arched dorsally in the median plane, with proximal bifurcation (Figure 139b; Hill & Harrison 1987).

Skull small but moderately robust for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region of medium relative breadth; rostrum of medium relative length and breadth (Table 25, p. 603). Profile of forehead region (viewed laterally) moderately concave. No occipital helmet. Inner upper incisor unicuspid. Outer upper incisor usually less than half height of inner incisor, sometimes barely reaching above cingulum of inner incisor. Anterior upper premolar minute, usually not visible above gum; canine and posterior premolar usually in contact. Lower molars nyctalodont. Dental formula: $2^{123}/_{3123} = 34$.

Geographic Variation No subspecies currently recognized (e.g. Simmons 2005). Possibly, individuals from desert habitats in Algeria, Libya, Somalia and Sudan are larger on average than those from non-desert habitats in West Africa (Burkina, Ghana, Nigeria and Senegal), but data from West Africa are very limited.

Desert specimens. FA: 29.5 (25–34) mm, $n = 21$; GLS: 11.6 (10.8–12.4) mm, $n = 9$.

West African specimens. FA: 27.4 (25–30) mm, $n = 3$; GLS: 11.4 (11.1–11.7) mm, $n = 3$.

Similar Species Eight other *Pipistrellus* and *Eptesicus* occur in North Africa:

Pipistrellus ariel. Wings without white hind-border. Lower molars myotodont. Outer upper incisor about two-thirds length of inner upper incisor. S Egypt and Sudan.

P. savii. Larger (FA: 34–38 mm; GLS: 12.8–14.6 mm). Ears broader than their length. Wings without white hind-border. Lower molars myotodont.

P. kuhlii. Dorsal pelage dark sepia brown or dark brown. Forearm sometimes longer (32.8 [29–37] mm). Skull dimensions usually greater (GLS: 13.2 [12.3–13.8] mm; GWS: 8.5 [8.0–8.9] mm; C–M³: 4.8 [4.4–5.2] mm). Anterior lower premolar less reduced. Relative skull dimensions different (Table 25, p. 603).

P. pipistrellus. Wings without distinct white hind-border. Inner upper incisor bicuspid.

P. hanaki. Dorsal pelage brown to rusty-brown. Wings without distinct white hind-border. Inner upper incisor bicuspid. Outer upper incisor almost as high as inner incisor.

P. rueppellii. Mid-ventral pelage pure white; face and ears dark; throat sometimes pale rusty-brown.

Eptesicus (2 spp.). Larger (FA: 38–52 mm; GLS: 15.3–20.1 mm). Anterior upper premolar always absent. Lower molars myotodont.

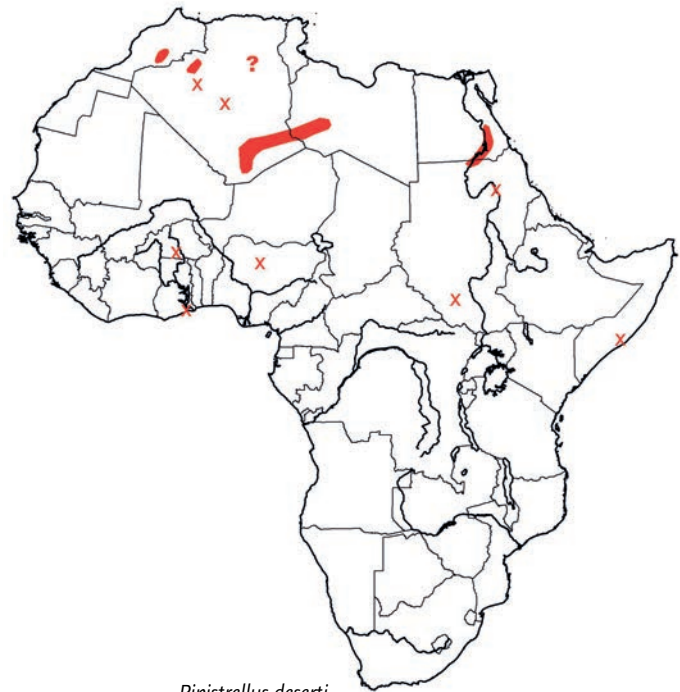

South of the Sahara, three other *Pipistrellus* also have lower molars nyctalodont and inner upper incisors unicuspid (see also Table 27, pp. 608):

P. aero. Dorsal pelage dark brown. Wings without white hind-border. Kenya and possibly Ethiopia.

P. hesperidus. Dorsal pelage greyish-brown, reddish-brown, dark brown or blackish. Wings without white hind-border. Very little overlap in distribution.

P. rusticus. Dorsal pelage reddish-brown to medium brown. Wings sometimes without white hind-border. Forehead region of skull straight to weakly concave. Distribution possibly only overlapping in West Africa, Sudan and Kenya.

Distribution Endemic to Africa. Appears to have a disjunct distribution with long-standing records in northern part of the Sahara Arid BZ in S Morocco, C and S Algeria, S Libya and in the Nile Valley in Egypt and N Sudan (Gaisler *et al.* 1972, Benda *et al.* 2004d), and a more recent record from the Somalia–Masai BZ in Somalia (unpublished museum record). Recently, specimens from non-desert habitats (mainly in the Sudan Savanna and Guinea Savanna BZs) in Burkina (Koopman *et al.* 1978), Ghana (Decher *et*

Pipistrellus deserti

al. 1997), Nigeria, S Sudan and possibly Senegal, have been identified as *P. deserti* (unpublished museum records). There are also records from the Somalia–Masai BZ in Kenya and Uganda (not mapped), but Koopman (1975) suggests these are probably erroneous and might represent *Pipistrellus nanus helios* (= *P. helios* or *P. cf. helios*) or *Pipistrellus somalicus*.

Habitat Mostly recorded from isolated localities in the most arid regions of the Sahara, where local conditions (e.g. oases) provide day-roosts and an adequate supply of insects (Happold 1984, P. Benda unpubl.). In Egypt and N Sudan, all records have been near the Nile R. where palm trees are present (Qumsiyeh 1985 as *P. aegyptius*). Qumsiyeh also reported that, elsewhere, it has been collected only in areas where palm trees occur, but possibly this is because both *P. deserti* and palms are species that inhabit desert oases. The more recent southern records (see above) indicate that *P. deserti* also occurs in Sudanian woodland including areas with abundant *Isoberlinia*, and perhaps in *Acacia–Commiphora* deciduous bushland and thicket. On the Accra Plains of Ghana, it was recorded in a mosaic of grassland and *Zanthoxylum–Capparis* thicket (Decher 1997, Decher *et al.* 1997).

Abundance Uncertain: probably rare. However, *P. deserti* was recorded as the most common species of bat in oases in S Libya (P. Benda unpubl.).

Adaptations Little is known. In Fezzan, Libya, roosts by day in abandoned buildings (P. Benda unpubl.). One colony, in an old mosque in the Gabroon oasis, occupied a narrow fissure between a wooden ceiling joist and a wall, and in other oases, it was found in fissures in a mud wall and between ceiling joists. There is an unconfirmed report that this species was also found in a tomb in Sudan (Hufnagl 1972). In Algeria, local people said that it roosts in hollow palm trees (Qumsiyeh 1985).

Foraging and Food In Egypt, ca. 100 individuals gradually appeared in a garden in Luxor during the evening while it was still light. They foraged for insects by slow-hawking 0.5–3 m above the ground. In Fezzan, S Libya, they were observed foraging from near ground level up to 10 m above ground in several surveyed oases (P. Benda unpubl.).

Echolocation Search-phase call-shape steep FM/QCF. Intensity high; start-frequency not known; end-frequency and peak-frequency 42–43 kHz (P. Benda pers. comm.). Very similar to echolocation calls of *P. kuhlii*.

Social and Reproductive Behaviour In Gabroon Oasis (see above), 15 members of a colony of ca. 30 individuals were adult or subadult ♀♀, suggesting they belonged to a maternity colony (P. Benda unpubl.). Several other roosts in Fezzan, S Libya, were occupied by single ♂♂. A sample of 16 from the aggregation in Luxor, comprised one ♂ and 15 ♀♀, of which 12 were lactating (Gaisler *et al.* 1972). This supports the suggestion that *P. deserti* forms maternity colonies.

Reproduction and Population Structure Litter-size and reproductive chronology not known. At 24°41'N (Luxor, Egypt) 12 of 15 ♀♀ captured between 26 Apr and 3 May were lactating (Gaisler *et al.* 1972).

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

Pipistrellus eisentrauti EISENTRAUT'S PIPISTRELLE

Fr. Pipistrelle d'Eisentraut; Ger. Eisentrauts Zwergfledermaus

Pipistrellus eisentrauti Hill, 1968. Bonn. Zool. Beitr. 19: 45. Dikume-Balue, Rumpi Highlands, Western Province, Cameroon.

Taxonomy Traditionally *Pipistrellus eisentrauti*. Subsequently classified as *P. (Hypsugo) eisentrauti* by Hill & Harrison (1987) and Koopman (1993), *Pipistrellus eisentrauti* by Menu (1987), *P. (Pipistrellus) eisentrauti* by Koopman (1994). Based on the karyotype of one specimen from Rwanda (SMF 79444; 2n = 42; aFN = 58), *eisentrauti* was placed in *Hypsugo* by Volleth & Heller (1994), Heller *et al.* (1994), Volleth *et al.* (2001) and Simmons (2005). However, the Rwandan specimen is larger than any other known specimen of *P. eisentrauti* and is not considered here to represent *P. eisentrauti*. *Pipistrellus eisentrauti* formerly included *bellieri* (e.g. Koopman 1993, Koopman *et al.* 1995) but, following Heller *et al.* (1994), *bellieri* is provisionally included here in *P. crassulus* pending further investigation of its status. Based on mitochondrial DNA of one specimen from Côte d'Ivoire (ROM 100532), *eisentrauti* is tentatively placed in *Nycticeinops* by Hofer & Van Den Bussche (2003), but this specimen is considered here to represent *P. crassulus bellieri*. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (usually all visible above gum), five lower cheekteeth and two upper incisors on each side; small and short-eared for a vespertilionid (FA: 33–36 mm; E: 10–13 mm); wings dark without white hind-border; dorsal pelage dark; dorsal and ventral hairs bicoloured; lower molars myotodont; inner upper incisor bicuspid; posterior margin of tragus without sharp angle. Sexual dimorphism: no data. Pelage soft,

dense; mid-dorsal hairs 6–7 mm. Dorsal pelage dark, slightly reddish, brown; hairs described as unicoloured by Hill (1968), but the holotype (ZFMK 68.5) and one paratype (ZFMK 68.6) are bicoloured (J. Fahr pers. comm.), and a further five specimens (BMNH 84.1684–88) are also bicoloured. Another paratype (BMNH 67.2129) does have unicoloured dorsal pelage, but this specimen is not considered here to represent *P. eisentrauti* (see below). Ventral pelage slightly paler and more beige; hairs with blackish-brown at base. Ears blackish-brown, 34 (24–39)% of FA, n = 17; inner margin convex with small basal lobe, outer margin almost straight; tip rounded. Tragus length probably just under half of E but very variable in preserved material; broadest at mid-point; anterior margin almost straight except for slight basal concavity; posterior margin slightly and smoothly convex for most of its length; tip rounded. Wings and interfemoral membrane dark blackish-brown; wings without white hind-border. Baculum short and stout, base bilobed and tip widened, shaft broad and flattened dorsoventrally (Figure 140e, BMNH 84.1684; Hill & Harrison 1987).

Skull large and robust for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region relatively narrow; rostrum massive, deep, relatively long and broad (Table 25, p. 603). Supraorbital region expanded so dorsal surface of rostrum is roughly pentagonal in outline (cf. *P. inexpectatus*, *P. permixtus*). Braincase inflated frontally; profile of forehead region (viewed laterally) very weakly concave (almost straight). Sagittal crest very weakly developed; lambdoid crests weakly developed; no distinct

occipital helmet. Inner upper incisor long, bicuspid. Outer upper incisor unicuspid (but with a low lateral cingulum cusp), slender and small, ca. half to two-thirds the height of inner incisor (reaching almost the height of the posterior cusp of the inner incisor). Anterior upper premolar usually present, comparatively minute to medium-sized, usually visible above gum, displaced lingually into recess between canine and posterior premolar, which are almost in contact. Lower molars of the holotype and one paratype (ZFMK 68-5, 68-6), and two other specimens (BMNH 84.1684, 84.1686) are myotodont (no data for the other specimens in this series). Another paratype (BMNH 67.2129) is nyctalodont but, based on its more concave forehead and unicoloured dorsal pelage, it is not considered here to represent *P. eisenrauti*. Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation Apparently none.

Similar Species Five other African *Pipistrellus* have dark wings; bicoloured dorsal hairs; myotodont lower molars; and have (or might have) distributions overlapping that of *P. eisenrauti* (Table 26, p. 606):

Pipistrellus capensis. Inner upper incisor weakly bicuspid before tooth is worn, then unicuspid. Anterior upper premolar absent. Forehead region of skull usually straighter, although sometimes also weakly concave.

P. guineensis. Ventral pelage dark rusty-brown, sometimes speckled. Anterior upper premolar absent.

P. crassulus crassulus. Ventral hairs unicoloured. Forearm shorter (28–32 mm, $n = 9$). Skull notably flattened, braincase usually low, rostrum lower and less massive. Zygomatic arches comparatively slender; zygomatic width almost always less (9.1 [8.9–9.2] mm, $n = 3$).

P. musculus. Smaller (FA: 23–26 mm; GLS: 10.3–11.4 mm).

P. brunneus. Inner upper incisor unicuspid. Anterior upper premolar absent.

Distribution Endemic to Africa. Known (with certainty) only from the Afromontane–Afroalpine BZ of Cameroon. Records from DR Congo (Lukolela; AMNH 86916), Uganda (Kampala, BMNH 66.1171), Kenya (Kirono Forest, BMNH 78.951), Kenya (AMNH, CM) and Somalia (Varty & Hill 1988) do not sufficiently resemble the holotype and paratype of *P. eisenrauti* to be considered representatives of this species (V. Van Cakenberghe unpubl.).

Habitat The holotype was found in montane forest at 1100 m in the Rumpi Highlands, and the paratype (ZFMK 68.6) in montane forest at 1100 m on Mt Kupé. Also in the Cameroon Highlands, Fedden & Macleod (1986) mist-netted 26 individuals (including BMNH 84.1684–88 mentioned above). Of these, one was netted at 750 m, and nine were netted at 850 m, over stagnant pools in the dried-up beds of water-courses that flow torrentially only in the wet season and create natural flyways through the forest. Another two were netted over a running stream in an area of disturbed forest and cultivated land. Twelve others were netted over stagnant pools in montane forest (two at 1100 m and ten at 1500 m), another was netted over a stream running through forest at 1950, and one was mist-netted at 2235 m over the shore of a lake surrounded by forests that showed signs of disturbance. At this site, many bats were seen

Pipistrellus eisenrauti

flitting through the vegetation overhanging the lake and flying over the lake, but the only species netted were *P. eisenrauti* and *Miniopterus* sp. (referred to as *M. schreibersii*, but not likely to be this species).

Abundance Uncertain.

Remarks Some observations of reproductive condition were published by Fedden & Macleod (1986) but they are hard to interpret and are not conclusive. Apparently nothing else is known about the biology of this species.

Conservation IUCN Category: Data Deficient.

If restricted to Cameroon Highlands, the geographic range is very restricted and this species is probably threatened.

Pipistrellus grandidieri YELLOW PIPISTRELLE

Fr. Pipistrelle jaune; Ger. Gelbe Zwergfledermaus

Pipistrellus grandidieri (Dobson, 1876). Ann. Mag. Nat. Hist., ser. 4, 18: 500. Zanzibar.

Taxonomy Previously *Vesperugo* (*Vesperus*) *flavescens* Seabra, 1900. Traditionally *Eptesicus flavescens*. Subsequently classified as *P. (Neoromicia) flavescens* by Hill & Harrison (1987) and Koopman (1994), as *E. (Neoromicia) flavescens* by Koopman (1993) and as *Neoromicia flavescens* by Simmons (2005). Placed in collective group *Attalepharca* (Menu 1987). Hayman & Hill (1971) suggested that *P. flavescens* might be conspecific with *Pipistrellus melckorum*, but Koopman (1975, 1993, 1994) considers it to be a valid species. The holotype of *flavescens* was destroyed in a fire and subsequently many authors disregarded the original description of *flavescens* and relied on 'topotypes' at MNHN. However, these do not seem to represent the original *flavescens*: instead they appear to represent *P. capensis angolensis* (Hill & Carter 1941) and *flavescens* appears to be a *nomen dubium* and should be replaced by *grandidieri* (Thorn *et al.* 2007). Following Thorn *et al.* (2007), *grandidieri* is also the sole member of a newly created subgenus of *Pipistrellus*, *Afropipistrellus*. Synonyms: *angolensis*. Subspecies: two. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth (but often only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (8–13 mm); FA: 33–38 mm; dorsal pelage pale; dorsal and ventral hairs unicoloured; wings dark, usually without white hind-border; lower molars myotodont, inner upper incisor bicuspid; profile of forehead region of skull almost straight. A poorly known species. Pelage silky with slight sheen; mid-dorsal hairs ca. 5–6 mm. Dorsal pelage pale brown; hairs unicoloured. Ventral pelage very slightly paler and usually yellowish; hairs unicoloured. Head with muzzle short, broad. Ears brown, subtriangular, relatively short. Tragus length ca. 60% of E in one freshly killed specimen but very variable in preserved material; broadest at mid-height; anterior margin straight; posterior margin smoothly convex with conspicuous basal lobe; tip rounded. Wings blackish-brown, slightly translucent, usually without white hind-border. Interfemoral membrane blackish-brown; tail fully enclosed by membrane. Baculum fairly straight, tapering to a slender distal tip, basally bifurcated, and the margins somewhat bent ventrally to form a half-pipe covering the urethra for the basal two-thirds. Laterally the shaft decreases apically in its diameter (Thorn *et al.* 2007).

Skull comparatively large and robust for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region of medium relative breadth; rostrum of medium relative length but relatively broad (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave to almost straight. Occipital helmet sometimes present. Inner upper incisor bicuspid. Outer upper incisor almost as high as inner upper incisor. Anterior upper premolar minute, displaced lingually and sometimes not visible above gum, or absent; canine and posterior upper premolar in contact. Lower molars myotodont. Dental formula: $^{2113}/_{3123} = 32$ or $^{2123}/_{3123} = 34$.

Geographic Variation Two subspecies of *P. grandidieri* are recognized by Thorn *et al.* (2007).

Pipistrellus g. angolensis. Cameroon, Angola and Malawi.

P. g. grandidieri. East Africa and Burundi (and presumably Somalia and Zanzibar I., see below).

Similar Species Four other African *Pipistrellus* have dark wings; unicoloured dorsal hairs; myotodont lower molars (Table 26, p. 606):

Pipistrellus c. crassulus. Smaller (FA: 28–32 mm; GLS: 12.5–13.2 mm).

P. c. bellieri. Almost always smaller (FA: 28–33 mm; GLS: 12.1–13.6 mm). Ventral hairs bicoloured, various shades of pale brown. Guinea, Liberia, Côte d'Ivoire.

P. muscivulus. Much smaller (FA: 23–26 mm; GLS: 10.3–11.4 mm).

P. brunneus. Dorsal pelage reddish-brown to dark chocolate brown. Ventral hairs bicoloured. Posterior margin of tragus angular so tragus appears truncated. Inner upper incisor unicuspid. Anterior upper premolar absent.

Distribution Endemic to Africa. Known only from mostly isolated localities in the Rainforest BZ, Eastern Rainforest–Savanna Mosaic, Afromontane–Afroalpine BZ, Coastal Forest Mosaic BZ and Zambezian Woodland BZ. Recorded from Cameroon, Uganda, Burundi, Somalia, Zanzibar I., Angola and Malawi. According to Thorn *et al.* (2007), *P. grandidieri* has also been recorded from 04° 20' S, 39° 32' E on the southern coast of Kenya, and from 10 localities on or near the NE coast of Tanzania.

Pipistrellus grandidieri

Habitat Three specimens from Malawi were mist-netted over a pool in montane evergreen forest at the foot of Mulanje Mt and one was mist-netted over a stream in remnant riverine forest in a mosaic of farmland and wetter Zambezian miombo woodland on the Shire Highlands (Happold & Happold 1997). In Somalia, recorded in riverine forest in the Jubba Valley (Varty & Hill 1988 as *P. eisentrauti*). In Tanzania, recorded from lowland forest, secondary forest, undifferentiated riverine forest, forest edge and sub-montane forest at altitudes of 120–800 m: often netted near and over streams and a pond, and once netted in forest near a rocky outcrop (Thorn *et al.* 2007). The two localities in Angola are in the wetter miombo woodland zone, the Cameroon localities in the lowland rainforest zone and the Burundi locality in undifferentiated afromontane vegetation, but no habitat details are available for these records. Known altitudinal range: 120–1633 m.

Abundance Apparently rare to extremely rare throughout its range, but the taxonomy of this species is controversial and it might be more abundant than the records indicate.

Remarks One individual from Malawi had low aspect ratio and low wing-loading. It was only moderately manoeuvrable in flight; minimum radius of banked turns >50 cm; able to fly across a 1×1×1 m enclosure, but not able to fly a complete circuit. Able to take off from ground.

Pipistrellus guineensis GUINEAN PIPISTRELLE

Fr. Pipistrelle de Guinée; Ger. Guinea-Zwergfledermaus

Pipistrellus guineensis (Bocage, 1889). J. Sci. Math. Phys. Nat. Lisboa, ser.2, 1: 6. Bissau, Guinea-Bissau.

Taxonomy Originally *Vesperugo guineensis*. Traditionally *Eptesicus guineensis*. Subsequently classified as *Pipistrellus* (*Neoromicia*) *guineensis* by Hill & Harrison (1987) and Koopman (1993, 1994), and as *Neoromicia guineensis* by Simmons (2005). Horáček & Hanák (1986) indicate that *guineensis* might belong to *Hypsugo*. This species was called *pusillus* by Hayman & Hill (1971), but specimens of *P. somalicus* have also been identified as *pusillus* (Koopman 1975). The specific status of *guineensis* has been discussed by Rosevear (1962), Koopman (1965), Kock (1969a) and Lagen *et al.* (1974), but it is currently regarded as a valid species, closely related to *P. capensis* and *P. somalicus*. Synonyms: *rectitragus*. Subspecies: two. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short (6–12 mm); FA: 23–35 mm; dorsal pelage dark; dorsal and ventral hairs bicoloured; wings dark, sometimes with white hind-border; lower molars myotodont, inner upper incisor bicuspid; profile of forehead region of skull weakly concave. Sexes similar in colour: ♀♀ reported larger than ♂♂ by Koch-Weser (1984), but this was not evident from our data (unpublished museum material). Pelage soft and dense; mid-dorsal hairs 6–8 mm. Dorsal pelage dark rusty-brown; hairs much darker at base. Ventral pelage similar or slightly paler than dorsal pelage, sometimes speckled;

Conservation IUCN Category (as *P. flavescens*): Data Deficient.

*Seabra (1900)

Key References Hill & Carter 1941; Thorn *et al.* 2007.

Victor Van Cakenberghe & Meredith Happold

hairs bicoloured. Rostrum short and slender. Ears dark greyish-brown, subtriangular, rounded at base, relatively short. Tragus length ca. 40% of E; broadest at mid-height; anterior margin concave; posterior margin without abrupt angle, but with small triangular lobe at base; tip rounded (Figure 136g). Wings dark greyish-brown, sometimes with narrow white hind-border. Interfemoral membrane dark greyish-brown; tail almost completely enclosed by membrane; postcalcareal lobe with convex border. Baculum as in Figure 141c (Hill & Harrison 1987).

Skull small and gracile for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region of medium relative breadth; rostrum low, relatively short and narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave (Figure 137c). No occipital helmet. Inner upper incisor large, bicuspid or conspicuously stepped. Outer upper incisor small, less than half height of inner incisor. Anterior upper premolar absent. Lower molars myotodont (M. D. Carleton pers. comm.).

Geographic Variation Two subspecies are recognized by Kock (1969a), Koopman (1994) and Simmons (2005):

P. g. guineensis: Senegal to Central African Republic. FA: 24–30 mm, n = 280; GLS: 10.7–11.8 mm, n = 22.

P. g. rectitragus: Ethiopia, S Sudan, NE DR Congo. FA: 26–31 mm, n = 26; GLS: 10.9–11.6 mm, n = 17.

Similar Species Six other African *Pipistrellus* also have dark wings; bicoloured dorsal hairs; myotodont lower molars; and have (or might have) distributions overlapping that of *P. guineensis* (Table 26, p. 606):

Pipistrellus capensis. Ventral pelage white, whitish or cream. Inner upper incisor weakly bicuspid before tooth is worn, then unicuspid. Skull longer (GLS: 12.0–15.4 mm).

P. inexpectatus. Ventral pelage reddish-cream; hairs unicoloured. Anterior upper premolar present although not visible above gum.

P. zuluensis. Dorsal hairs bicoloured or tricoloured. Ventral pelage pale greyish-brown. Inner upper incisor usually unicuspid. Geographic range might overlap in Uganda, S Sudan and Ethiopia.

P. ariel. Ventral pelage greyish-cream. Inner upper incisor unicuspid. Anterior upper premolar present although not always visible above gum.

P. somalicus. Mid-ventral pelage brown; hairs only faintly bicoloured. Inner upper incisor unicuspid or weakly bicuspid.

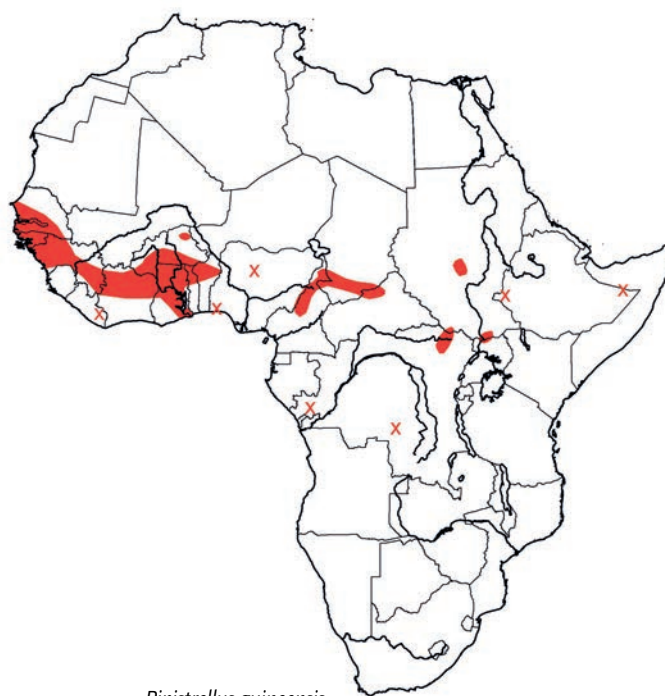

P. eisentrauti. Ventral pelage palish brown. Anterior upper premolar usually present and visible above gum.

Distribution Endemic to Africa. Recorded disjunctly mainly from the Sudan Savanna and Guinea Savanna BZs and the Rainforest–Savanna Mosaics, with some very marginal records in the Rainforest BZ and one isolated record in the Somalia–Masai Bushland BZ. Recorded from most countries from Senegal to Ethiopia and Somalia, and from Congo and DR Congo. Recently recorded from Ghana (Kock *et al.* 2002). Reports of *P. guineensis* (as *Eptesicus pusillus* and/or *E. guineensis*) in Angola (Hayman 1963, Feiler 1990) and Tanzania (Swynnerton & Hayman 1951) are more likely to refer to *P. somalicus* (Koopman 1975). Subsequently recorded for first time in Liberia by Monadjem & Fahr (2007).

Habitat In West Africa, apparently inhabits the various woodland savannas, reaching the coast where climate and vegetation permit, as on the Accra Plains (Ghana) and at Conakry (Guinea) (Decher *et al.* 1997). On the Accra Plains, two individuals were recorded near an artificial waterhole in a mosaic of grassland and thicket, and one was recorded amongst savanna trees near rocky cliffs. Others have been recorded in gardens (Koch-Weser 1984, Decher 1997). Thirty specimens for which data are available were recorded between 420 and 2166 m.

Abundance Uncertain. Rarely recorded.

Remarks Based on morphometric data, Fenton & Bogdanowicz (2002) suggest that this species forages by slow-hawking, possibly over water. Two lactating ♀♀ were recorded on 2 Nov 1991 at Yendi in the Northern Region of Ghana (Decher *et al.* 1997).

Pipistrellus guineensis

Conservation IUCN Category: Least Concern.
Geographic range comparatively large.

Pipistrellus hanaki HANÁK'S PIPISTRELLE

Fr. Pipistrelle de Hanák; Ger. Hanáks Zwergfledermaus

Pipistrellus hanaki Hulva & Benda, 2004. Acta Chiropterologica 6: 207. Upper part of the Wadi Al Kuf (Jabal Akhdar Mts.), ca. 5 km south-west of Al Bayda, Al Jabal Al Akhdar District, 32° 44' N, 21° 41' E; ca. 495 m. Cyrenaica, Libya.

Taxonomy Formerly considered to represent *Pipistrellus pipistrellus* until recognized as a distinct species, belonging to the *Pipistrellus pygmaeus* genetic lineage, by Benda *et al.* (2004b) on the basis of morphology and genetics. Synonyms: *pipistrellus* of Hürka, 1982, Qumsiyeh & Schlitter 1982, Hanák & Elgadi 1984, Le Berre 1990, Amr & Qumsiyeh 1993 and others: see Benda *et al.* 2004b for complete list. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (11–13 mm); FA: 31–33 mm; wings dark with pale or translucent hind-border; dorsal pelage brown to rusty-brown; dorsal and ventral hairs bicoloured; lower molars nyctalodont; inner upper incisor bicuspid; profile of forehead region of skull moderately concave; posterior margin of tragus without sharp angle. Sexes similar. Pelage dense, soft; mid-dorsal hairs ca. 5 mm. Dorsal pelage brown to rusty-brown: hairs with basal half dark rusty-brown, terminal half pale brown to rusty-brown. Ventral pelage pale brown, moderately paler than dorsal pelage: hairs dark rusty-brown with terminal third umber brown. Naked skin of muzzle and around eyes dark brown. Ears dark brown, subtriangular with rounded tip. Tragus length ca. half of E; almost equally broad along most of its length; anterior margin rather straight, posterior margin smoothly convex with basal lobe; tip rounded. Wing and interfemoral membranes dark brown; wings with no hind-border or with a pale or translucent hind-border, but never with a distinct white hind-border (cf. *P. kuhlii*, *P. deserti*). Penis uniformly pale greyish-brown with a short, pale median stripe only on the most distal part of the foreskin (cf. *P. pipistrellus*). Baculum long, thin, bifurcated at both ends, ca. 1.8 mm long (Figure 139c; Benda *et al.* 2004b).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase relatively high and narrow; interorbital region relatively narrow; rostrum of medium relative length and breadth (Table 25, p. 603). Profile of forehead region (viewed laterally) moderately concave (Figure 137b). Occipital helmet almost absent; sagittal crest almost absent. Inner upper incisor bicuspid (posterior cusp ca. two-thirds height of main cusp). Outer upper incisor almost as high as inner incisor. Canines comparatively massive (cf. *P. pipistrellus*). Anterior upper premolar present, well developed, visible above gum, displaced linguallly; canine and posterior premolar not in contact. Lower molars nyctalodont. Dental formula $^{2123}/_{3123} = 34$.

Geographic Variation None.

Similar Species Seven other *Eptesicus* and *Pipistrellus* occur in North Africa (excluding *P. ariel* in S Egypt) (see also Table 26, p. 606):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

Pipistrellus hanaki

P. pipistrellus. Skull shorter (GLS: 11.5 [11.0–11.9] mm). Forearm on average shorter (FA: 29.6 [28–33] mm). Dorsal pelage darker and with greyish tinge. NW Africa (the Maghreb).

P. kuhlii. Wings with distinct white hind-border. Inner upper incisor unicuspid. Outer upper incisor much smaller than inner incisor.

P. deserti. Dorsal pelage pale sepia brown to pale yellowish-brown (sometimes with greenish tint). Wings with broad white hind-border. Inner upper incisor unicuspid. Outer upper incisor much smaller than inner incisor.

P. savii. Larger (FA: 34–38 mm; GLS: 12.8–14.6 mm). Anterior upper premolar minute, not visible above gum, sometimes absent. Lower molars myotodont.

Eptesicus (2 spp.). Larger (FA: 38–52 mm; GLS: 15.3–20.1 mm). Anterior upper premolar always absent. Dorsal pelage very pale brown.

Distribution Endemic to Africa. Known only from the Mediterranean Coastal BZ in the Cyrenaica region of Libya. Recorded from at least eight localities within this region (Benda *et al.* 2004b).

Habitat Recorded from Mediterranean shrubland from sea level to ca. 500 m, and from mosaics of shrubland and agricultural land (including pastures and fields). Has been found in wadis (ravines or valleys with flowing water in wet season) and highlands.

Abundance No information.

Remarks As yet, very little is known about the habits of this species. Its search-phase echolocation calls are steep FM/QCF sweeps with end-frequency (QCF component) and peak-frequency 45 kHz (as in *P. pipistrellus* from NW Africa).

Reproduction and Population Structure Litter-size: 2 ($n = 7$). Reproductive chronology not known. At 32–33°N (Cyrenaica, Libya), 7 of 8 ♀♀ were pregnant (near term) in late May, suggesting reproductive synchrony; no data for other months. The testes of seven adult ♂♂ captured between early Mar and early Apr ranged in size from 1.5 to 3.5 mm in length and 1.2 to 2.5 mm in width (Qumsiyeh & Schlitter 1982).

Predators, Parasites and Diseases Ectoparasites include bat-flies *Basilina mediterranea* and *B. daganiae* (Diptera: Nycteribiidae) (Hürka 1982, Amr & Qumsiyeh 1993).

Conservation IUCN Category: Data Deficient.

Distribution apparently restricted to ca. 3000–5000 km², which implies need for extreme conservation priorities. Consequently, Benda *et al.* (2004b) suggest that the IUCN Category should be Vulnerable.

Pipistrellus cf. helios SAMBURU PIPISTRELLE

Fr. Pipistrelle du Saburu; Ger. Samburu-Zwergfledermaus

Pipistrellus cf. helios auctorum non Heller, 1912. Smiths. Misc. Coll. 60 (12): 3. Merelle Water, 30 miles south Mt Marsabit, Kenya.

Taxonomy Formerly considered a subspecies of *P. nanus* (e.g. Koopman 1975, 1993). However, Hill & Harrison (1987) raised *helios* to specific status on the basis of its bacular morphology, and Peterson (1987) also indicated that *helios* is a distinct species. Behavioural differences between *P. helios* (O'Shea 1980, as *P. nanus*) and *P. nanus* (Happold & Happold 1990b, 1996) support this conclusion. Furthermore, the lower molars of specimens studied by Harrison & Hill (1987) are myotodont (unlike those of *P. nanus*, which are nyctalodont) and these specimens have glands on the interfemoral membrane (which are not present in *P. nanus*) (see details below). *Pipistrellus helios* was placed in *P. (Hypsugo)* by Hill & Harrison (1987) and, as a subspecies of *P. nanus*, was placed in *P. (Pipistrellus)* by Koopman (1993, 1994). It is placed in *Neoromicia* by Simmons (2005), as is *nanus* (as *Neoromicia nana*). Synonyms: none. Chromosome number: not known.

Since this profile was written, D. E. Wilson examined the holotype of *helios* and reported to Teresa Kearney (pers. comm.) that its lower molars are nyctalodont (as in *P. nanus*), and there were no glands on its interfemoral membrane. This indicates that the material on which this profile is based applies to another taxon that is referred to here as *P. cf. helios*. Specimens BMNH 69.207 and HZM 2.4086, referred to as *helios* by Hill & Harrison (1987), have myotodont lower molars and glands on the interfemoral membrane, and therefore are considered here to represent *P. cf. helios*: the lower molars of the third specimen referred to as *P. helios* by Harrison & Hill (1987) have not been examined. Voucher specimens for the studies by O'Shea (1980) have glands on the interfemoral membrane but it is not known if the lower molars are myotodont or not. Other specimens labelled *helios* in the BMNH (presumably identified by J. Edwards Hill) have myotodont

lower molars and most (but not BMNH 69.207) have glands on the interfemoral membrane (see below), and are therefore considered here to represent *P. cf. helios*. Based on lower molars, it is unlikely that both *cf. helios* and *nanus* belong to *Neoromicia*.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (usually all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (5–11 mm); FA: 26–30 mm; dorsal pelage pale; dorsal hairs tricoloured; ventral hairs bicoloured; wings dark with white hind-border; lower molars myotodont; inner upper incisor bicuspid; profile of forehead region of skull strongly concave; posterior margin of tragus with abrupt angle; glands usually present on interfemoral membrane. Sexes similar in colour; ♂♂ on average larger than ♀♀. Pelage soft, dense; mid-dorsal hairs 5–7 mm. Dorsal pelage pale brown to pale yellowish-brown; hairs tricoloured with basal quarter blackish-brown, central half pale creamy-fawn, terminal quarter pale brown. Ventral pelage paler; hairs dark blackish-brown with pale brown at tip. Ears naked, pale brown with rounded tip; relatively short. Tragus length probably ca. half of E but very variable in preserved material; broadest above mid-height; hatchet-shaped (anterior margin slightly to distinctly concave, posterior margin with abrupt, obtuse angle above mid-height, tip rounded) (as in *P. tenuipinnis*, Figure 136c). Wings very dark brown to blackish with very narrow to moderate white hind-border. Interfemoral membrane semi-translucent and markedly paler than wings (cf. *P. nanus*). Most adults of both sexes have a pair of glands, 1.2–3.8 mm in diameter, one on each side of

the tail, on the proximal quarter of the interfemoral membrane; glands best seen when backlit and magnified. Baculum as in Figure 139c (Hill & Harrison 1987).

Skull small and gracile for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region of medium relative breadth; rostrum relatively short and narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) strongly concave. No occipital helmet. Inner upper incisor bicuspid and broad. Outer upper incisor reaching the posterior cusp of the inner incisor. Anterior upper premolar well developed, displaced lingually (occasionally only somewhat displaced), visible above gum; in some specimens this tooth is missing on one side. Lower molars myotodont. Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation No definite information. Thomas O'Shea (pers. comm.) observed *P. nanus*-like thatch-roosting bats with tail-glands, and leaf-roosting *P. nanus* without tail-glands living sympatrically in Côte d'Ivoire, which suggests that a form very similar to *P. cf. helios* occurs in West Africa. Furthermore, specimens of a myotodont *Pipistrellus* with hatchet-shaped tragus and glands on the tail (but bicoloured dorsal hairs) (BMNH 3.2.3.62 [Côte d'Ivoire], 11.1.22.5, 65.757, 65.758 [Ghana], 5.12.1.2-4 [Nigeria], labelled as *P. nanus*) might also indicate geographical variation and a much wider distribution for *P. cf. helios*, but this needs confirmation.

Similar Species None. Although some other African species of *Pipistrellus* have myotodont lower molars and bicuspid inner upper incisors (Table 26, p. 606), none of these have tricoloured dorsal hairs, hatchet-shaped tragus and paired glands on the interfemoral membrane.

Distribution Endemic to Africa. *Pipistrellus cf. helios* is mainly found in the Somalia–Masai Bushland BZ and Coastal Forest Mosaic BZ. Primarily distributed in Kenya (except NW corner and much of

the NE side), with an extension along the coast to Somalia and along the Jubba and Webi Shabeelle rivers in S Somalia. The type locality for true *P. helios* lies in this area. The range for *P. cf. helios* also extends westward into E and NE Uganda and extreme S Sudan, and as far as L. Victoria in Tanzania. There is an isolated record from Djibouti (Funaioli & Lanza 1968), which needs confirmation. The possibility that *P. cf. helios* (or a closely related form) occurs in West Africa is mentioned above. It is also possible that *P. cf. helios* (or a closely related form) occurs in the Kruger N. P., South Africa (see profile *P. nanus*).

Habitat In eastern Africa, widely recorded in dry habitats (*Acacia*–*Commiphora* deciduous bushland, mosaic of East African evergreen bushland and secondary *Acacia* wooded grassland, and semi-desert grassland and shrubland), but also recorded from East African coastal forest mosaic, *Isoberlinia* woodland, undifferentiated montane vegetation and mosaics of lowland rainforest and secondary grassland. Sixty-five specimens for which data are available were found between 400 and 1333 m.

Abundance Uncertain.

Adaptations At Masalani, near Kibwezi, Kenya, the roosting, foraging, social and reproductive behaviour and reproduction of *P. cf. helios* were studied by O'Shea (1980, as *P. nanus*) and O'Shea & Vaughan (1980, as *P. nanus*). Aspect ratio low; flight characteristics not known. Roosts by day, and also intermittently at night, between overlapping, vertically hanging fronds of palms *Phoenix reclinata*, in small crevices around the edges of roofs thatched with bundles of palm fronds, and in crevices in vertical sections of thatch used to cover walls. Becomes torpid during the day. The function of the glands on the interfemoral membranes of adults of both sexes is not known; in adult ♂♂, there was no correlation with testes size.

Foraging and Food Forages for small insects by slow-hawking 2–5 m above ground, frequently within 1 m of vegetation.

Echolocation Search-phase call-shape steep FM/QCF. Intensity high; start-frequency ca. 115 kHz; end-frequency 65 kHz (as in *P. nanus*) (n = ?; O'Shea & Vaughan 1980, as *P. nanus*).

Social and Reproductive Behaviour At Masalani, *P. cf. helios* roosted singly or in groups of 2–12; group-composition highly labile (O'Shea 1980). Prior to parturition in Nov, all ♀♀ left the study area, presumably to establish a maternity colony elsewhere. At other times, most adult ♂♂ roosted singly; others usually roosted with one ♀ or, less frequently, with two or more ♀♀. Adult ♀♀ usually roosted with one ♂; occasionally with other ♀♀ without a ♂. Adult ♂♂ almost never roosted with other ♂♂. Prime roost sites (large enough to accommodate a ♂ and one or more ♀♀) were scarce; ♂♂ showed roost-fidelity, competed aggressively for prime roosts and defended them by fighting intruders and by chasing them in flight. Males often carried scars and bite wounds. Activities in and near roosts occurred throughout the night: some bats rested; territorial ♂♂ patrolled outside their roosts and chased other ♂♂ away; ♀♀ flew along the roof, stopping to circle at roosts of ♂♂ and apparently choosing where to spend the day. Males vocalized at their roosts and ♀♀ were attracted to the most vocal ♂♂. Although

♀ ♀ roosted with several ♂ ♂ sequentially, they avoided roosting with most ♂ ♂ more than once, and roosted more frequently with certain others. These observations suggest that the mating system resembles one based on resource-defence polygyny.

Reproduction and Population Structure Litter-size: 2 (n = 16). At 02°18'S (Masalani, inland Kenya), reproductive chronology is restricted seasonal monoestry, with births in Nov, lactation until late Dec or early Jan. No evidence of testicular activity until Mar, when testes descended; they remained descended (scrotal) from Apr through Sep. Copulation not observed but assumed to occur from May to Aug (when ♂ ♂ were most vocal at their roosts). Ovulation and fertilization assumed to occur in late Aug (O'Shea 1980).

Sex ratio at birth not known (cf. *P. nanus*). Overall ratio of ♂ ♂ to ♀ ♀ in the resident population at Masalani was 2 : 1. A seasonal phase of dispersal occurred in late May to mid-Jun, when some adult bats left and others joined the population.

Predators, Parasites and Diseases Predators include Heart-nosed Bats *Cardiaderma cor* and probably arboreal snakes (especially *Psammodphis* sp.), which were found in thatch near the roost sites (O'Shea 1980). Ectoparasites include a bat-fly *Basilia ansifera* (Diptera: Nycteribiidae) (Theodor 1956).

Conservation IUCN Category: Data Deficient.

Pipistrellus hesperidus DUSK PIPISTRELLE

Fr. Pipistrelle hespéride; Ger. Abendstern-Zwergfledermaus

Pipistrellus hesperidus (Temminck, 1840). Monographies de Mammalogie ou description de quelques genres de mammifères, dont les espèces ont été observées dans les différents Musées de l'Europe, 2: 211. Type locality given by Temminck (1840) as 'the shores of the Red Sea towards the coasts (or at the side of) Abyssinia', a topographic description not definitely identifiable (Kock 2001) but likely to be the coast of Eritrea (not the coast of Ethiopia, and not Shewa province as indicated by Simmons 2005).

Taxonomy Originally *Vespertilio hesperida*. Synonyms: *broomi*, *fuscatus*, *subtilis*. Subspecies: uncertain (see Geographic Variation). Until recently, this species was considered as *Pipistrellus kuhlii*, although Göpfert *et al.* (1995) and Volleth *et al.* (2001) had shown that specimens from Europe and North Africa have a different chromosome number (2n = 44) to specimens from southern Africa and Madagascar (2n = 42). Awaiting further description, southern African and Malagasy specimens were called *P. 'cf. kuhlii'* as a way of distinguishing this taxon from Palearctic *P. kuhlii*. Kock (2001b) reinstated the name *Pipistrellus hesperidus* for sub-Saharan populations, which he identified as a species distinct from *P. kuhlii* on morphological and parasitological characters.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (usually all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (9–15 mm); FA: 29–38 mm; wings palish or dark without white hind-border; dorsal pelage various shades of brown but not rusty-brown; dorsal and ventral hairs bicoloured; lower molars nyctalodont, inner upper incisor unicuspid; profile of forehead region of skull moderately concave; posterior margin of tragus without sharp angle. Not easily distinguished from *P. rusticus*. Sexes similar. Pelage dense, soft; mid-

dorsal hairs ca. 5 mm. Dorsal pelage variable – some individuals paler (greyish-brown or reddish-brown), others darker (dark brown to almost black); hairs with basal three-fifths blackish-brown or black, therefore either faintly or conspicuously bicoloured. Ventral pelage cream, creamy-orange, orangey-red, reddish-brown or dark brown (pale when dorsal colour is pale and vice versa); hairs with basal three-fifths dark brown or blackish-brown. Ventral pelage not noticeably paler in pelvic region; no all-white hairs there. Naked skin of muzzle and around eyes is dark brown. Ears dark reddish-brown, subtriangular with rounded tip. Tragus length ca. half of E; widest just below mid-height; anterior margin almost straight; posterior margin smoothly convex with small basal lobe; tip rounded. Wing-membrane colour pale brown (when pelage is pale) to blackish-brown (when pelage is dark); no white hind-border. Interfemoral membrane paler than wing-membranes. Baculum as in Figure 139d (Kearney *et al.* 2002).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region of medium relative breadth; rostrum relatively long but of medium relative breadth (Table 25, p. 603). Dorsal margin of orbit slightly but obviously inflated – viewed dorsally, the upper rim of the orbit bulges outwards (cf. straight in *P. kuhlii*). Profile of forehead region (viewed laterally) moderately concave. Rostral emargination

comparatively wide and U-shaped (cf. *P. kuhlii*). Inner upper incisor unicuspid, without posterior basal cusp (Kock 2001b). Outer upper incisor less than half height of inner incisor but reaching above its cingulum. Anterior upper premolar present, medium-sized to minute, usually visible above gum, within tooththrow to fully displaced lingually; canine and posterior premolar well separated or in contact. Posterior upper molar large, comparatively broad with a long third ridge and a wide gap between protocone and metacone (cf. *P. kuhlii*) (Kock, 2001b). Lower molars nyctalodont. Dental formula: $^{2123}_{3123} = 34$.

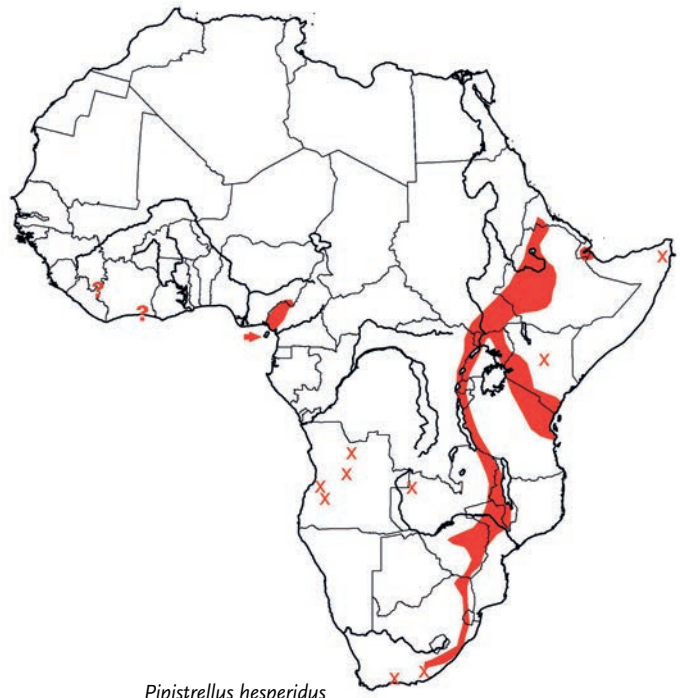

Geographic Variation The distinction of subspecies and allocation of many populations to subspecies still remains uncertain and requires further investigation (Koopman 1994, Kock 2001b). Koopman (1994) tentatively recognized two subspecies within the geographic range of *P. hesperidus*: *fuscatus* (East Africa) and *subtilis* (south-east Africa); Simmons (2005) also recognizes these subspecies. In contrast, Kock (2001b) tentatively recognized *fuscatus* (East Africa) and *broomi* (south-east Africa). Kock (2001b) did not examine or identify any *subtilis* but he indicates that the definition and differentiation of *subtilis* from other species in the group containing *P. hesperidus* and *P. kuhlii* is still uncertain. Differences in size between specimens from East Africa and those from elsewhere in the geographic range of *P. hesperidus* are very slight.

Similar Species South of the Sahara, three other *Pipistrellus* also have lower molars nyctalodont and inner upper incisors unicuspid (Table 27, p. 608):

- Pipistrellus. aero.* Interfemoral membrane and wings alike in colour and translucency. Kenya and possibly Ethiopia.
- P. deserti.* Dorsal pelage pale sepia brown to pale yellowish-brown (sometimes with greenish tint). Wings with white hind-border. Distribution possibly only overlapping in West Africa, Sudan and Kenya.
- P. rusticus.* Dorsal pelage paler, more orange, and shorter. Profile of forehead region of skull straight to weakly concave. Wings sometimes with white hind-border.

Distribution Endemic to Africa. Recorded mainly from the eastern side of Africa, and mainly in the Somalia–Masai Bushland, Afromontane–Afroalpine, Coastal Forest Mosaic and Zambeian Woodland BZs, with one record in the South-West Cape BZ. Also recorded from the Zambeian Woodland BZ in Angola and W Zambia, and from the Rainforest BZ (Western and West Central Regions) in West Africa (although at least some of the specimens from West Africa might represent *P. crassulus bellieri*; J. Fahr pers. comm.).

Habitat Found in diverse habitats including lowland rainforest, montane forests, mosaics of montane forest and grassland and other montane vegetation, coastal forests, *Acacia–Commiphora* bushland and miombo woodland; never far from open water, and often in association with human settlements. In the north-east of its geographic range, recorded at sea level in Djibouti (Pearch *et al.* 2001) but also from 1800 to 3000 m in the Ethiopian Highlands (Largen *et al.* 1974). In Malawi, recorded mainly in montane forests, miombo woodland, farmlands with riverine and/or relict rainforests: from 800 to 2300 m; not recorded below 500 m (Happold & Happold 1997). In South Africa,

Pipistrellus hesperidus

recorded from most bioregions (although largely absent from Drier and Moist upland, Highland and Montane regions; Taylor, P. 1998).

Abundance Common in certain areas, while uncommon and localized at others.

Adaptations Aspect ratio low; wing-loading very low (M. Happold pers. comm.). Flight slow but acrobatic. Roosts by day in cracks in rock (including narrow cracks in exfoliating granite), behind loose bark of dead trees, in hollow trees, under roofs, and in crevices of buildings (Smithers & Wilson 1979, Rautenbach 1982, Happold *et al.* 1987). In Malawi, becomes torpid during day at ambient temperatures 21–24 °C (Happold & Happold 1988). Predicted mean maximum urine concentration comparatively high (4168 mOsmol/kg) (Happold & Happold 1988).

Foraging and Food Forages by slow-hawking in moderately cluttered spaces including between tree trunks, around and over canopies, over grass or dirt roads, in clearings, around houses (probably to pursue insects attracted to lights) and near water. Flight very acrobatic especially when pursuing insects that are concentrated in swarms or near lights. Emerges and begins foraging at dusk and remains active for several hours after sunset, with a smaller peak in activity at dawn (Rautenbach 1982).

Echolocation Search-phase call-shape (Malawi) steep FM/QCF (QCF 'heel' varies in duration). Intensity high; start-frequency 63–86 kHz; end-frequency 44–50 kHz; peak-frequency 45–50 kHz (usually 46–48 kHz); call-duration 2–7 ms (depending on duration of QCF 'heel') (26 bats, free-flying or tethered, 956 calls; M. Happold pers. comm.). In Zimbabwe, frequencies from 85 to 45 kHz were emitted by four bats flying in lighted room or veranda (Fenton 1975 as *P. kuhlii*). In South Africa, start-frequency (mean \pm S.D.) 65.7 \pm 5.3 kHz; end-frequency 48.7 \pm 0.4 kHz; peak-frequency

50.3 ± 0.4 kHz; call-duration 3.5 ± 0.5 ms (six bats, free-flying; Taylor 1999a).

Social and Reproductive Behaviour Roosts in groups of up to 12 individuals. Observed foraging in groups (Kingdon 1974, Rautenbach 1982, T. Kearney unpubl.). Mixed-sex groups of 2–10 have been mist-netted – the audible (to humans) calls of the first one caught would bring the others buzzing around the mist-net, in which case they were sometimes also caught (Kingdon 1974, T. Kearney unpubl.).

Reproduction and Population Structure Litter-size (Malawi, South Africa): usually two, rarely one (Rautenbach 1982, T. Kearney unpubl., M. Happold pers. comm.). Reproductive chronology uncertain. At 15–16°S in Malawi, 9 of 9 adult ♀♀ were not palpably pregnant, lactating or post-lactating in May–Jun; no data Jul–Sep; 14 of 17 were pregnant, two were lactating and one was reproductively inactive in Oct–Nov; 8 of 8 were lactating in Dec; no data Jan–Feb; 2 of 3 were post-lactating and one reproductively inactive in Mar–Apr. Volant young in Dec–Mar. These data are consistent with restricted seasonal monoestry with births in Nov–Dec at the beginning of the wet season (M. Happold pers. comm.). In South Africa, 4 of 4 ♀♀ were pregnant in Oct–Nov; 13 of 13 were not pregnant in Dec, Mar and May. Scrotal ♂♂ recorded only from Feb–Jun.

Predators, Parasites and Diseases Predators include Fiscal Shrikes *Lanius collaris* in Kenya (Schwan & Hikes 1979) and Little Sparrowhawks *Accipiter minullus* in South Africa (Kemp & Rautenbach 1987). Ectoparasites include bed-bugs *Cacodmus villosus* and *C. sparsilis* (Hemiptera: Cimicidae); a flea *Ischnopsyllus emminus* (Siphonaptera:

Ischnopsyllidae); and a bat-fly *Basilia robusta* (Diptera: Nycteribiidae) (Anciaux de Faveaux 1984, Kock *et al.* 1998b, Kock 2001b [host given as *P. rusticus*, re-identified as *P. hesperidus* by V. Van Cakenberghe]). In *P. kuhlii*, the bed-bug is replaced by *Cacodmus vicinus* and the flea by *Ischnopsyllus octactenus* (Kock 2001b).

Conservation IUCN Category: Least Concern.

Pipistrellus inexpectatus AELLEN'S PIPISTRELLE

Fr. Pipistrelle d'Aellen; Ger. Unerwartete Zwergfledermaus

Pipistrellus inexpectatus Aellen, 1959. Arch. Sci. Phys. Nat. Genève 12: 226. Ngaouyanga, Upper Benoue [= Benue] Valley, Cameroon.

Taxonomy Traditionally *Pipistrellus inexpectatus*. Subsequently classified as *P. (Pipistrellus) inexpectatus* by Hill & Harrison (1987), *Nycterikaupius inexpectatus* by Menu (1987), *P. (Hypsugo) inexpectatus* by Koopman (1993) and *P. (Pipistrellus) inexpectatus* by Simmons (2005). Hill & Harrison (1987) placed *inexpectatus* in the *kuhlii* group of the subgenus *Pipistrellus*, implying close relationship between *inexpectatus* and *kuhlii*. Furthermore, the holotype of *inexpectatus* was originally considered to represent *P. marginatus*, a name now considered to be a synonym of *P. kuhlii*. Often spelled *inexpectatus*, but this is incorrect. Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (10–13 mm); FA: 31–33 mm; dorsal pelage dark; dorsal hairs bicoloured, ventral hairs unicoloured; wings dark with white hind-border; lower molars myotodont, inner upper incisor bicuspid; profile of forehead region of skull weakly concave to almost straight. A poorly known

species. Dorsal pelage bright reddish-brown to dark brown; hairs with basal half blackish-brown. Ventral pelage reddish-cream; hairs darker at base. Ears brown, tip rounded; relatively short. Tragus length probably just under half of E but very variable in preserved material; broadest above mid-height; maximum breadth ca. one-third length of anterior margin; anterior margin concave as in Figure 136i (Rosevear 1965) or straight; posterior margin more or less smoothly convex with pronounced basal lobule; tip broadly rounded. Wings brown with distinct white hind-border. Interfemoral membrane paler than wings; tail extending slightly beyond membrane; postcalcarea lobe present but hardly visible. Bacular morphology not known.

Skull medium-sized but robust for an African *Pipistrellus*. Braincase relatively low but of medium relative breadth; interorbital region relatively narrow; rostrum of medium relative length and breadth (Table 25, p. 603). The rostrum has a well-developed lateral depression just above the infraorbital foramina (De Vree 1972) as in *P. anchietae* (J. E. Hill in Rautenbach *et al.* 1985) and some *P. capensis* (T. Kearney pers. comm): this character has not been checked in other species. Supraorbital region not so expanded that the dorsal

surface of the rostrum assumes a pentagonal outline (cf. *P. eisenrauti*). Profile of forehead region (viewed laterally) weakly concave to almost straight. No occipital helmet. Inner upper incisor long, bicuspid and straight; outer upper incisor small, approximately half the height of the inner incisor. Anterior upper premolar minute, almost always not visible above gum; canine and posterior premolar in contact. Lower molars myotodont. Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation None recorded.

Similar Species Four other African *Pipistrellus* also have dark wings, bicoloured dorsal hairs and myotodont lower molars, and have (or might have) distributions overlapping that of *P. inexpectatus* (Table 26, p. 606):

Pipistrellus capensis. Inner upper incisor weakly bicuspid before tooth is worn, then unicuspid. Anterior upper premolar absent. Ventral pelage white, whitish or cream.

P. guineensis. Ventral pelage dark rusty-brown, sometimes speckled; hairs bicoloured. Anterior upper premolar absent.

P. somalicus. Dorsal and ventral hairs only faintly bicoloured; ventral pelage brown with darker brown bases. Inner upper incisor unicuspid or weakly bicuspid. Outer upper incisor hardly higher than cingulum of inner incisor. Anterior upper premolar absent.

P. eisenrauti. Ventral pelage palish brown. Wings without white hind-border. Dorsal surface of rostrum roughly pentagonal in outline.

Distribution Endemic to Africa. Known from the Guinea Savanna BZ and the Northern Rainforest–Savanna Mosaic in Sierra Leone, Ghana, Benin, Nigeria and Cameroon. There are some specimens from elsewhere that have, at some time, been identified with *P. inexpectatus* (and sometimes with *P. eisenrauti*), but their identities are still controversial and provisionally they are not considered here to represent *P. inexpectatus*. These include specimens from DR Congo (Lukolela; AMNH 86916), Uganda (Kampala, BMNH 66.1171), Kenya (Kirono Forest, BMNH 78.951), Kenya (AMNH, CM). A specimen from Sudan, recorded as *P. inexpectatus* by Aellen (1959), is too young to be identified (Koopman 1975). According to E. Thorn, D. Kock & J. Cuisin (pers. comm.), specimens from Kenya in the CM belong to another species, altogether different from both *P. inexpectatus* and *P. eisenrauti*.

Habitat The type locality is Guinea woodland (Rosevear 1965), in a valley of the Upper Benue R. in Cameroon. No detailed descriptions of habitat seem to be available.

Remarks Very little is known about this species. The only reproductive data available refer to a single lactating ♀ recorded in September at ca. 1° S in Uganda (Bwindi Forest) (Kityo & Kerbis 1996). However, no voucher specimen was referenced or any

Pipistrellus inexpectatus

information on identifying characters. In view of the erroneous identifications from that area (see Distribution), the animal's identity could not be confirmed and therefore its locality is not mapped.

Conservation IUCN Category: Data Deficient.

***Pipistrellus kuhlii* KUHL'S PIPISTRELLE**
Fr. Pipistrelle de Kuhl; Ger. Weißbrandfledermaus

Pipistrellus kuhlii (Kuhl, 1817). Die Deutschen Fledermäuse. Hanau, p. 14. Trieste, Italy.

Taxonomy Originally *Vespertilio kuhlii*. Traditionally *Pipistrellus kuhlii*. Subsequently classified as *P. (Pipistrellus) kuhlii* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005), and *Pipistrellus kuhlii* by Menu (1987) and Volleth *et al.* (2001). Until recently, *P. kuhlii* was considered to be a very stable and well-defined species, represented in North Africa by the form *kuhlii* and south of the Sahara by several forms, including *fuscatus* and *broomi*, which differed in a number of small details (e.g. wings without white hind-border). Then specimens from North Africa and Europe were found to have a different chromosome number ($2n = 44$) to that of specimens from southern Africa and Madagascar ($2n = 42$) (Rautenbach *et al.* 1993, Göpfert *et al.* 1995, Volleth *et al.* 2001), and the latter were sometimes referred to as *P. cf. kuhlii*. Kock (2001b) reinstated the name *Pipistrellus hesperidus* for most of the sub-Saharan forms (see species profile). Consequently, this profile deals only with *P. kuhlii* in North Africa. The specific name is sometimes spelled *kuhli*, *kühli* or *kühlii*, but *kuhlii* is the original spelling (Bogdanowicz & Kock 1998). Synonyms in Africa: *marginatus*, *pallidus* and possibly *minuta* (but *minuta* is considered here more likely to be a synonym of *P. deserti*). Subspecies: pending further analysis, none recognized here (see Geographic Variation). *Pipistrellus deserti* is considered to be a subspecies of *P. kuhlii* by P. Benda & M. Ruedi (unpubl.) but, pending confirmation, *deserti* is tentatively retained here as a distinct species. Chromosome number: $2n = 44$, aFN = 50 (Volleth *et al.* 2001).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (but sometimes only four clearly visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (8–15 mm); FA: 29–37 mm; wings dark with white hind-border; dorsal pelage dark to pale; dorsal and ventral hairs bicoloured; lower molars nyctalodont; inner upper incisor unicuspid; profile of forehead region of skull moderately to weakly concave; posterior margin of tragus without sharp angle; outer upper incisor very small. Not easily distinguished from *P. deserti*. Sexes similar. Pelage soft, dense, fairly fluffy; mid-dorsal hairs 5–7 mm. Dorsal pelage varying from pale yellowish-brown, sepia brown (= olive brown) to dark rusty-brown; hairs bicoloured, dark brown or dark greyish-brown at base. Ventral pelage same as dorsal pelage or paler and greyer; hairs blackish-brown at base. Ears brown to blackish-brown, subtriangular; tip rounded. Tragus length ca. half of E but very variable in preserved material; broadest just below mid-height; anterior margin almost straight, posterior margin smoothly convex; tip rounded. Wings blackish-brown with white or pale hind-border, which varies in width (see Geographic Variation). Interfemoral membrane blackish-brown, brown or pale brown. Baculum strongly curved with bifurcations both distally and proximally (Figure 139e; Hill & Harrison 1987).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase of medium relative height but relatively narrow; interorbital region relatively narrow; rostrum relatively long but of medium relative breadth (Table 25, p. 603). Profile of forehead

region (viewed laterally) moderately to weakly concave. Dorsal margin of orbit not inflated, therefore, viewed dorsally, upper rim of orbit is straight (cf. *P. hesperidus*). No occipital helmet. Rostral emargination comparatively narrow and V-shaped (cf. *P. hesperidus*). Inner upper incisor large, unicuspid but with a posterior basal cusp. Outer upper incisor very small, less than half height of inner incisor but reaching above its cingulum. Anterior upper premolar extremely small, hardly visible above gum, usually displaced lingually; canine and posterior premolar in contact. Posterior upper molar large, comparatively narrow with a short third ridge and a short distance between protocone and metacone (cf. *P. hesperidus*) (Kock, 2001b). Lower molars nyctalodont. Dental formula: $^{2123}/_{3123} = 34$.

Geographic Variation Based on pelage colour and the width and colour of the hind-border on the wing, three 'colour forms' (not taxa) can be recognized in North Africa (P. Benda pers. obs.):

Desert populations from oases of C Algeria and Libya (ca. 100–300 km inland). Dorsal pelage pale yellowish-brown; hind-border white, very broad (6–8 mm) and restricted to arm-wing.

Coastal populations widespread in North Africa from Egypt to Algeria (at least) and extraliminally in the eastern Mediterranean (Syria, Lebanon, Turkey, Greece). Dorsal pelage sepia brown (= olive brown); hind-border white, narrower (1 mm) and extending along entire posterior edge of the wing.

Populations in N Morocco (and extraliminally Spain). Dorsal pelage dark rusty-brown (as in *P. pipistrellus*); hind-border pale (not white), extremely narrow (maximum 0.3 mm) and restricted to arm-wing.

According to Lewis & Harrison (1962), colour variation is clinal in the extralimital E Mediterranean region, and also varies according to habitat, desert-living populations being much paler than those from along the Mediterranean coast. Gaisler *et al.* (1972) found both dark and pale individuals in the same locality (Abu Rawash, Egypt), but this variation might represent age differences – young animals being darker than adults.

Similar Species Seven other *Pipistrellus* and *Eptesicus* occur in North Africa (excluding *P. ariel* in S Egypt):

Pipistrellus deserti. Dorsal pelage pale sepia brown to pale yellowish-brown, sometimes with greenish tint (i.e. similar to *P. kuhlii* in geographically close desert populations but not similar to *P. kuhlii* from elsewhere); FA sometimes shorter (30.1 [25–34] mm). Skull dimensions usually smaller (GLS: 11.7 [10.8–12.4] mm; GWS: 7.8 [7.4–8.2] mm, C–M³: 4.2 [3.7–4.6] mm). Anterior upper premolar more reduced.

P. savii. Ears broader than their length. Wings without white hind-border. Inner upper incisor bicuspid. Anterior upper premolar not visible above gum or absent. Lower molars myotodont.

P. pipistrellus. Wings without distinct white hind-border. Skull shorter (GLS: 11.0–11.9 mm). Inner upper incisor bicuspid. Outer upper incisor almost same height as inner incisor (or at least as high as its secondary cusp).

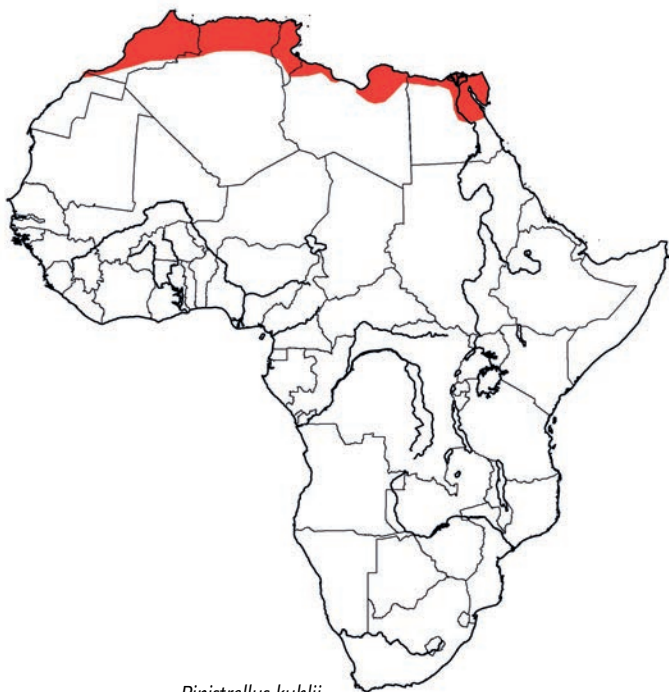

P. hanaki. Wings without distinct white hind-border. Inner upper incisor bicuspid. Outer upper incisor almost same height as inner upper incisor.

P. rueppellii. Mid-ventral pelage pure white; face and ears dark; throat sometimes pale rusty-brown.

Eptesicus (2 spp.). Larger (FA: 38–52 mm; GLS: 15.3–20.1 mm). Anterior upper premolar always absent.

Distribution In Africa, now considered to occur only in the Mediterranean Coastal and Afromontane–Afroalpine BZs and in the northern fringes of the Sahara Arid BZ, from Morocco to Egypt. Most records are north of 30°N. Records from Sahara Arid BZ south of 30°N in Algeria, and along the Nile Valley from C Egypt to N Sudan, are considered here to represent *P. deserti*. These include records from S Algeria, which Kowalski & Rzebik-Kowalska (1991) suggested might represent *P. deserti*. Previously thought to occur over a large part of Africa, but sub-Saharan specimens are now considered to represent *P. hesperidus* (Kock 2001b): so too are specimens from the Red Sea coast to Djibouti. Extralimittally: Mediterranean and Central Europe, S and C Ukraine as far north as Kiev, through Near East (including Arabian Peninsula) and through Caucasus to Kazakhstan, Afghanistan, Pakistan and SW Asia.

Habitat Widespread in the northern African vegetation zones bordering the Mediterranean Sea, and extending southwards to the northern fringes of the Sahara; recorded from sea level to 1500 m (in the Anti-Atlas Mts). In Algeria, often seen flying in towns and villages, often mist-netted (usually over water) in forests (including those in Atlas Mts) and in sparser vegetation, and common in oases in the northern Sahara (Kowalski & Rzebik-Kowalska 1991). Similarly,

very common in Mediterranean region of Morocco, Tunisia and Libya, and the most common species (and sometimes the only species) in the northern Saharan oases and in the Nile Delta in Egypt (P. Benda pers. obs.). In Egypt, occurs in deserts near cultivated areas, but not in Egyptian oases (Gaisler *et al.* 1972), and is commonly found around populated areas in N Egypt (Qumsiyeh 1985).

Abundance *Pipistrellus kuhlii* is one of the most common species of bats in the most northern parts of North Africa – possibly the most common.

Adaptations Flight speed of hunting bats (Eastern Europe) 4.0–4.5 m/sec (Schnitzler *et al.* 1987). The two colour types found in Abu Rawash (Egypt) by Gaisler *et al.* (1972) indicated to these authors that *P. kuhlii* might be a migratory species. However, this has not been confirmed – the different colours might be the result of age variation, and the records might include two age cohorts. Day-roosts include cracks and crevices in buildings (Anderson 1902).

Foraging and Food Forages by slow-hawking in comparatively open habitats (Barak & Yom-Tov 1989). At Oran in Algeria, activity is bimodal. The first peak begins soon after the bats emerge from their day-roosts (usually a little before sunset) and ends soon after sunset. A second, less marked, peak occurs around sunrise and the last individuals return to their roosts in full morning light (Kowalski & Rzebik-Kowalska 1991). In Israel, *P. kuhlii* hunts insects attracted to street lights but, unlike the insects, the bats never fly closer than 1.5 m to the lights (for unknown reasons). Some individuals hunt singly or in groups of 2–3, but the majority hunt in groups of 4–5, possibly because the echolocation calls of this number of bats disturb the insects sufficiently to cause them to disperse away from the lights – which makes them easier to catch (Barak & Yom-Tov 1989). On several occasions in North Africa, groups of *P. kuhlii* were observed flying together at sunset, but it was not clear if this represented group-hunting or swarming after emergence from the day-roosts (P. Benda pers. obs.). Faeces, collected in Israel, contained Lepidoptera, Coleoptera (Scarabaeidae, Dytiscidae and Curculionidae), Diptera (Chironomidae and Tipulidae), Hymenoptera (Formicidae), Hemiptera (Lygaeidae), Homoptera (Delphacidae and Cicadellidae) and Neuroptera (Feldman *et al.* 2000).

Echolocation For *P. kuhlii* from Eastern Europe, flying high in open (probably above 8 m) search-phase call-shape shallow FM. Intensity high; bandwidth 3–6 kHz; end-frequency 35–40 kHz; peak-frequency ca. 42 kHz; call-duration 8–12 ms. When these bats come closer to obstacles, search-phase call-shape becomes steep FM/QCF; intensity high; bandwidth ca. 35 kHz; end-frequency 35–40 kHz; call-duration shortened to 8–6 ms (Schnitzler *et al.* 1987). In sequences of calls, the end-frequency of search-phase calls is kept rather constant; the range of end-frequencies (35–40 kHz) reflects variation between different individuals.

Social and Reproductive Behaviour In a fort near Biskra, Algeria, and in old ruined tombs at Oaurgla, Algeria, generally only one individual was found in each occupied hole (Anderson 1902).

Reproduction and Population Structure Litter-size (Tunisia, Libya): one ($n = 3$) or 2 ($n = 18$) (Baker *et al.* 1974, P. Benda pers.

obs.). Reproductive chronology in Africa not known (data inconclusive). In Tunisia, 15 of 15 ♀♀ were pregnant on 25 Apr (crown–rump length of embryos 5–11 mm); 1 of 3 was lactating and the other two neither pregnant nor lactating on 5 Jun; and 1 of 1 was not pregnant on 19 Nov (Baker *et al.* 1974). At 36° 09' N (Sétif, Algeria), a pregnant ♀ was reported on 8 May, and two subadult ♀♀ on 16 Dec; and nearby, at Djemila, a colony included two lactating ♀♀, five juveniles and an adult ♀ on 11 Sep (Gaisler 1983). At 31° 02' N (Sinawan oasis, Libya), a colony comprised of three pregnant and five lactating ♀♀ was found on 8 May; whereas at 32° 43' N (Cyrenaica, Libya), one lactating and three pregnant ♀♀ were found on 22 May, and at 32° 28' N and 31° 47' N (Tripolitania, Libya), five lactating ♀♀ were found on 27 May and four on 28 May (P. Benda pers. obs.): this indicates that, in Libya, births occur earlier in the S desert populations than in the Mediterranean populations. In Egypt, 'parturition occurs in May' (Anderson 1902) but no year-round data are given, and in the Nile Delta, three non-lactating adult ♀♀ were found in Sep (P. Benda pers. obs.).

Predators, Parasites and Diseases Predators, in Morocco, include owls *Bubo ascalaphus*, *Strix aluco* and *Asio capensis* (Aulagnier 1989). Remains of *P. kuhlii* were also found in pellets of Barn Owls *Tyto alba* in Israel, Iran and Syria (J. Obuch pers. comm.), as well as in pellets of the owls *Asio otus* in Israel and Syria, *Athene noctua* in Syria and Iran, and *Strix aluco* in Turkey. Ectoparasites in Africa include bed-bugs *Cacodmus tunetanus*, *C. vicinus*, *Cimex pipistrelli* (Hemiptera: Cimicidae); fleas *Ischnopsylla octactena*, *I. consimilis*, *Nycteridopsylla ancyluris* (Siphonaptera: Ischnopsyllidae); bat-flies *Basilia daganiae*, *B. robusta* (Diptera: Nycteribiidae); ticks *Ixodes vespertilionis*, *Peplonyssus*

cruciplica (Acari: Ixodidae); and four species of mites (Theodor 1956, Hoogstraal & Traub 1963, Anciaux de Faveaux 1984, Kock 2001b).

Conservation IUCN Category: Least Concern (based on African and extralimital data).

Pipistrellus cf. melckorum MELCK'S PIPISTRELLE

Fr. Pipistrelle des Melcks; Ger. Melcks Zwergfledermaus

Pipistrellus cf. melckorum (auctorum non Roberts, 1919). Ann. Transvaal Mus. 6: 113. Kersfontein, Berg River, Cape Province, South Africa.

Taxonomy Specimens from the Cape, South Africa, described by Roberts as *Eptesicus melckorum*, are now considered synonymous with *P. capensis* (Thorn 1988). Recent chromosome GTG-banding and morphometric analyses support this conclusion (Rautenbach *et al.* 1993); furthermore, specimens from the type locality of *melckorum* have the same chromosome number as *capensis*, 2n = 32 (T. Kearney unpubl.). There is, however, a more northerly distributed species fitting the description of *melckorum*, which is distinct from *capensis* on basis of chromosome number, 2n = 40; aFN = 50 (Rautenbach *et al.* 1993), and which has unusually heavy molars (Koopman 1994). Specimens of this species have been called cf. *melckorum* pending renaming. Specimens from the northern population have been referred to as *Eptesicus (Neoromicia) melckorum* by Koopman (1993), *Pipistrellus (Neoromicia) melckorum* by Hill & Harrison (1987), and as *Neoromicia melckorum* by Simmons (2005). Its placement in *Neoromicia* is questioned by Hoofer & Van Den Bussche (2003). Subspecies: none. Chromosome number: see above.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper

and five lower cheekteeth and two upper incisors on each side; ears separated and short (10–16 mm); FA: 32–39 mm; wings dark with or without white hind-border; dorsal pelage pale to dark; dorsal and ventral hairs bicoloured; lower molars myotodont; inner upper incisor unicuspid or weakly bicuspid; profile of forehead region of skull straight to weakly concave. Sexes similar. Pelage soft, dense; mid-dorsal hairs ca. 6 mm. Dorsal pelage pale brown to dark brown, often with slight silvery or golden sheen; hairs with basal two-thirds dark brown to blackish-brown. Ventral pelage chocolate brown to silvery-brown on chin and throat, becoming brownish-cream on chest and belly, and cream or greyish-white in pelvic region; hairs mostly dark brown with paler tips; pelvic hairs all-cream or greyish-white except, according to Ansell (1967), in Zambian specimens. Naked skin of muzzle and around eyes brown. Ears brown, subtriangular with rounded tip. Tragus length just over half of E; breadth nearly constant for most of length; anterior margin concave; posterior margin smoothly convex with shallow, folded basal lobe; tip rounded (Figure 136j). Wing-membranes brown, dark brown or blackish-brown, slightly translucent; usually with narrow white hind-border, sometimes with no hind-border, rarely with conspicuous

hind-border. Interfemoral membrane paler and more translucent. Baculum as in Figure 141e and f (Kearney *et al.* 2002).

Skull large and robust for an African *Pipistrellus*. Braincase relatively low and narrow; interorbital region relatively narrow; rostrum relatively long but of medium relative breadth (Table 25, p. 603; material not confirmed by its chromosomes). Profile of forehead region (viewed laterally) straight to weakly concave. Occipital helmet weakly developed. Inner upper incisor unicuspid or weakly bicuspid. Outer upper incisor reaching above cingulum of inner incisor (ca. one-third height of inner incisor). Anterior upper premolar absent. Molars unusually heavy. Lower molars myotodont. Dental formula $2^{113}/_{3123} = 32$.

Geographic Variation No information. No subspecies recognized because the true extent of the species is not yet clearly identified.

Similar Species One African *Eptesicus* and four other African *Pipistrellus* also have dark wings; bicoloured dorsal hairs; myotodont lower molars; and have (or might have) overlapping geographic ranges (Table 26, p. 606):

Pipistrellus capensis. Forearm on average shorter (31.9 [28–38] mm).

Tail on average shorter (30.5 [25–38] mm). Inner upper incisor weakly bicuspid before wearing. Molars not as massive. Widespread south of Sahara.

P. somalicus. Smaller (FA: 22–31 mm; GLS: 11.3–12.9 mm). Braincase relatively high; profile of forehead region weakly concave.

P. zuluensis. Skull shorter (GLS: 11.3–12.9 mm). Forearm usually shorter (27–33 mm). Braincase relatively high; profile of forehead region weakly to moderately concave; no occipital helmet. Inner upper incisor sometimes bicuspid.

P. anchietae. Inner upper incisor unicuspid. Anterior upper premolar present although not visible above gum. Skull shorter (GLS: 11.2–13.7 mm).

Eptesicus hottentotus. Much larger (FA: 45–54 mm; GLS: 16.9–21.5 mm).

Distribution Endemic to Africa. Recorded from scattered localities in the Zambezian Woodland BZ and marginally in the Somalia–Masai Bushland BZ, from Tanzania, Zambia, Malawi, Zimbabwe, Mozambique and South Africa (Ansell 1960a, 1967, 1978, Smithers & Lobão Tello 1976, Happold *et al.* 1987, Hill & Harrison 1987, Rautenbach *et al.* 1993, Cotterill 1996a).

Habitat Poorly known but includes woodlands and riverine forests. In Malawi, recorded from miombo woodland at 1000 m (Kasungu N. P.) and from open areas between houses in the Administration Camp, in miombo woodland at 500 m (Liwonde N. P.); not recorded from montane areas, or from the more arid habitats of the Lower Shire Valley (100 m) (Happold *et al.* 1987).

Abundance Uncertain, but appears uncommon. Rarely recorded in Malawi (Happold & Happold 1997).

Remarks Aspect ratio low; wing-loading very low ($n = 1$; M. Happold pers. comm.). Flies with great manoeuvrability; turns

Pipistrellus cf. melckorum

by banking (minimum radius <25 cm) and by stalling-and-twisting; sustained flight in a 1×1×1 m enclosure for up to two circuits/flight (1 bat, 10 flights; M. Happold pers. comm.). Day-roosts not known. Ansell (1960a) indicated that '*Eptesicus melckorum*' roosts inside buildings but he cites Roberts (1951) as the source of this information, and therefore it probably pertains to *P. capensis* (see Taxonomy). Echolocation search-phase call-shape near obstacles (Malawi) steep FM/QCF (Figure 118e); intensity high; start-frequency 56–72 kHz; end-frequency 37–39 kHz; peak-frequency 39–41 kHz; call-duration 2–6.5 ms (1 bat, tethered, 31 calls; M. Happold pers. comm.). Data for bats tentatively identified as '*melckorum*' by Taylor (1999a) are now known to pertain to *P. capensis*. Ectoparasites include a bed-bug *Aphranzia cf. barys* (Diptera: Cimicidae) (Kock *et al.* 1998b).

Conservation IUCN Category (as *Pipistrellus melckorum*): Data Deficient.

Pipistrellus musculus MOUSE-LIKE PIPISTRELLE

Fr. Pipistrelle murine; Ger. Mäuschen-Zwergfledermaus

Pipistrellus musculus Thomas, 1913. Ann. Mag. Nat. Hist., ser. 8, 11: 316. Dja River, Bitye, 2000 ft (610 m), Cameroon.

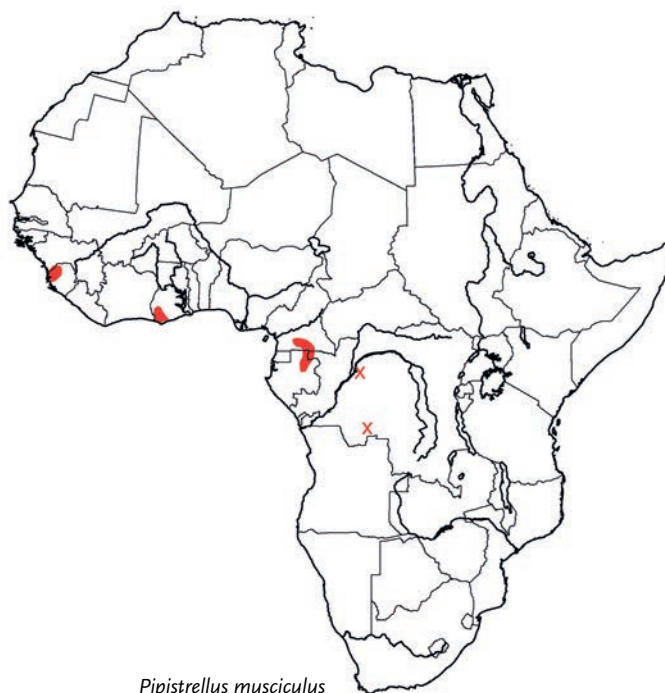

Taxonomy Traditionally *Pipistrellus musculus*. Subsequently classified as *P. (Hypsugo) musculus* by Hill & Harrison (1987) and Koopman (1993) and as *Hypsugo musculus* by Simmons (2005). Placed in collective group *Attalepharca* by Menu (1987), and in *Pipistrellus* by Heller *et al.* (1994). Placed in *Pipistrellus*, in the *hesperus* group by Koopman (1994) – *Pipistrellus hesperus* is a North American pipistrelle. Based on its incisors and premolars, Hill & Harrison (1987) speculated that *P. musculus* might be closely related to *P. nanus* but, based on other characters, including cuspidation of lower molars, this opinion is not held here. Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth (but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (8–11 mm); FA: 23–26 mm; pelage dark; dorsal and ventral hairs unicoloured; wings dark without white hind-border; lower molars myotodont; inner upper incisor bicuspid; profile of forehead region of skull weakly concave. A poorly known species. Sexes similar in colour. Pelage soft, dense; mid-dorsal hairs 3–4 mm. Both dorsal pelage and ventral pelage dark umber-brown; hairs unicoloured. Ears very dark blackish-brown; inner margin strongly convex at base, then straight. Tragus length ca. one-third of E; narrow, anterior margin straight; posterior margin smoothly convex; tip rounded. Wings dark blackish-brown; no white hind-border (Thomas 1913b). Interfemoral membrane dark blackish-brown; postcalcareal lobe well developed. Penis relatively short. Bacular morphology not known.

Skull small and gracile for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region relatively broad; rostrum relatively short but of medium relative breadth (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave. No occipital helmet. Inner upper incisor bicuspid; outer and inner upper incisors almost equal in size. Anterior upper premolar minute, often not visible above gum, displaced lingually, sometimes absent. Lower molars myotodont. Dental formula: $2^{113}/_{3123} = 32$ or $2^{123}/_{3123} = 34$.

Geographic Variation None recorded.

Similar Species Four other African *Pipistrellus* have dark wings; unicoloured dorsal hairs; myotodont lower molars (Table 26, p. 606):

Pipistrellus musculus

Pipistrellus grandidieri. Much larger (FA: 33–38 mm; GLS: 13.8–14.7 mm).

P. crassulus bellieri. Larger (FA: 28–33 mm; GLS: 12.1–13.6 mm). Ventral pelage various shades of pale brown; ventral hairs bicoloured. Anterior upper small, visible.

P. crassulus crassulus. Larger (FA: 28–32 mm; GLS: 12.5–13.2 mm). Ventral pelage dark brown or reddish-brown.

P. brunneus. Much larger (FA: 33–38 mm; GLS: 13.0–14.1 mm). Inner upper incisor unicuspid.

Distribution Endemic to Africa. Found in the Rainforest BZ and the Northern Rainforest–Savanna Mosaic in West Africa and central Africa. As yet, only recorded from Sierra Leone, Ghana, Cameroon, Gabon and DR Congo. Gaps in the distribution are likely to be the result of insufficient sampling.

Habitat Mainly rainforest habitats, but recorded from Guinea savanna in Sierra Leone, and on the coast as well as in the rainforest zone in Ghana (Grubb *et al.* 1998).

Remarks Flight very rapid. An adult ♂ and ♀ and two young were taken from the hollow stem of a Raphia Palm *Raphia vinifera* in Jun (BMNH). Another adult ♀ was caught in the hollow stem of another Raphia Palm (BMNH). Perret & Aellen (1956) captured some flying in the town of Foulassi in Cameroon, and Brosset (1966) observed some foraging in groups of 4–5, near the ground in the vicinity of buildings in Gabon. At 9–10° N in Sierra Leone, a lactating ♀ was collected in mid-May (USNM 547020).

Conservation IUCN Category: Data Deficient.

Pipistrellus nanulus TINY PIPISTRELLE

Fr. Pipistrelle miniscule; Ger. Kleine Zwergfledermaus

Pipistrellus nanulus Thomas, 1904. Ann. Mag. Nat. Hist., ser. 7, 14: 189. Efulen, Cameroon.

Taxonomy Traditionally *Pipistrellus nanulus*. Subsequently classified as *P. (Pipistrellus) nanulus* by Hill & Harrison (1987), Koopman (1993) and Simmons (2005), *Pipistrellus nanulus* by Menu (1987) and Heller *et al.* (1994), and *P. (Vansonia) nanulus* by Koopman (1994). Dieter Kock (pers. comm.) doubts the assignment to *Vansonia*. Placed in the *rueppellii* group by Hill & Harrison (1987). Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (7–11 mm); FA: 24–29 mm; dorsal pelage reddish-brown; dorsal hairs unicoloured, ventral hairs sometimes bicoloured; wings dark, usually without white hind-border; lower molars nyctalodont; inner upper incisor bicuspid; profile of forehead region of skull moderately concave; posterior margin of tragus without abrupt angle. Sexes similar. Pelage dense; mid-dorsal hairs 4–5 mm. Dorsal pelage reddish-brown; hairs unicoloured. Ventral pelage usually pale brown; hairs usually unicoloured but sometimes bicoloured, pale brown with darker base. Ears rather short and rounded. Tragus length ca. half of E but variable in preserved material, anterior margin almost straight; posterior margin smoothly convex with pronounced basal lobe; tip rounded (Figure 136k). Wings reddish-brown (similar to dorsal pelage); usually without white hind-border although a clear (translucent) hind-border is sometimes present. Interfemoral membrane reddish-brown; tail protruding slightly beyond membrane; postcalcarea lobe narrow. Penis enlarged; prepuce hairy. Baculum as in Figure 139f (Hill & Harrison 1987).

Skull small and gracile for an African *Pipistrellus*. Braincase relatively high and broad; interorbital region relatively broad; rostrum relatively short and broad (Table 25, p. 603). Profile of forehead region (viewed laterally) moderately concave. No occipital helmet. Inner upper incisor bicuspid. Outer upper incisor bicuspid, well developed, attaining

almost the height of the inner incisor. Anterior upper premolar comparatively medium to large, almost within toothrow or slightly displaced lingually, visible above gum and from the outside; canine and posterior premolar not in contact. Lower molars nyctalodont. Dental formula: $2^{123}/_{3123} = 34$.

Geographic Variation None recorded.

Similar Species Three other sub-Saharan *Pipistrellus* have nyctalodont lower molars and bicuspid inner upper incisors (Table 27, p. 608):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

P. nanus. Dorsal pelage not reddish-brown; hairs bicoloured. Tragus hatchet-shaped (posterior margin with abrupt angle). FA sometimes >29 mm.

P. permixtus. Dorsal hairs bicoloured. Only known from Dar-es-Salaam, Tanzania.

Distribution Endemic to Africa. Primarily known from the Sudan Savanna, Guinea Savanna and Rainforest BZs and the Northern Rainforest–Savanna Mosaic in West Africa, and recorded in most countries from Senegal to Cameroon, Gabon and Bioko I. There are some additional records from the Rainforest BZ and Eastern Rainforest–Savanna Mosaic in E DR Congo, Uganda and W Kenya.

Habitat No details available for most records. Occurs mainly in the rainforest zone but extends northwards into derived and Guinea savannas and riverine forests; 15 specimens for which data are available were recorded between 50 and 1833 m. Recorded flying over small streams and pools (Happold 1987, Decher *et al.* 1997). Recorded in a cocoa plantation on Bioko I. (Eisentraut 1964).

Abundance Uncertain.

Adaptations One individual flew into a hollow branch that was also occupied by a hive of wild bees (Lang & Chapin 1917b, as *P. musculus* but the specimen was re-identified as *P. nanulus* by Koopman 1965). Perret & Aellen (1956) captured some flying around in the town of Foulassi, Cameroon.

Foraging and Food Two were seen foraging at daybreak for insects swarming over a damp wallow (Lang & Chapin 1917b, as *P. musculus*).

Reproductive and Social Behaviour An 'enormous' colony was found in the roof of a European-style house in a cocoa plantation on Bioko I. (Eisentraut 1964).

Reproduction and Population Structure Litter-size: one or 2 ($n = 2$; Decher *et al.* 1997). Reproductive chronology not known. Two pregnant ♀♀ were recorded in Ghana in Jan (Decher *et al.* 1997). One lactating ♀, one non-pregnant and non-lactating ♀, and four ♂♂ with abdominal testes, were recorded in Côte d'Ivoire in Jan (Lim & Van Coeverden de Groot 1997).

Predators, Parasites and Diseases Ectoparasites include bed-bugs (Hemiptera: Cimicidae), which were found on the wings (Lang & Chapin 1917b, as *P. musculus*).

Conservation IUCN Category: Least Concern.

Widespread, comparatively common, no known threats.

Pipistrellus nanus BANANA PIPISTRELLE (BANANA BAT)

Fr. Pipistrelle naine; Ger. Bananenfledermaus

Pipistrellus nanus (Peters, 1852). Reise nach Mossambique, Säugeth., p. 63. Inhambane, Mozambique.

Taxonomy Originally *Vespertilio pipistrellus* var. *africanus*. Traditionally *Pipistrellus nanus*. Subsequently classified as *P. (Hypsugo) nanus* by Hill & Harrison (1987), *Pipistrellus nanus* by Menu (1987), *P. (Pipistrellus) nanus* by Koopman (1993) and *Neoromicia nana* by Volleth *et al.* (2001), Kearney *et al.* (2002) and Simmons (2005). Unlike all other pipistrelles placed in *Neoromicia* by Simmons (2005) and also unlike all African species placed in *Hypsugo* (Simmons 2005), *P. nanus* has nyctalodont lower molars, as have all African species in *Pipistrellus* (*sensu stricto*): therefore (based on this and other craniodental characters) the assignment of *P. nanus* to either *Hypsugo* or *Neoromicia* is dubious and, pending further investigation, it is retained here in *Pipistrellus* (*sensu stricto*). Koopman (1975) indicated that *africanus* Rüppell, 1842 is the senior synonym of *nanus* Peters, 1852.

However, *africanus* is seldom used and the International Commission on Zoological Nomenclature, Opinion 2120, has ruled that the name *nanus* is given precedence over the name *africanus* whenever the two are considered to be synonyms (Anonymous 2005). Synonyms, pending revision: *abaensis*, *africanus*, *culex*, *fouriei*, *meesteri*, *minusculus*, *pagenstecheri*, *pusillulus* and *stampflii*. Formerly included *helios* but, based on bacular and dental and/or behavioural data, *helios* was considered to be a distinct species by Hill & Harrison (1987) and (following M. Happold) by Simmons (2005) and others. However, it is now known that the above data refer to another form – profiled here as *P. cf. helios* – and therefore the status of *helios* and its relationship to *P. nanus* needs to be reassessed. Several other forms also have been considered specifically

distinct, or perhaps specifically distinct, by some authors; e.g. Perret & Aellen (1956) indicated that *culex* is a distinct species occurring in the Sudan and Sahel savanna zones. Peterson (1987), without including reasons, indicated that *australis* (now *meesteri*) is a distinct species, and that *minusculus* (including *fouriei* and *culex*) might be a distinct species. Koopman (1965) suggested that *stampflii* (= *minusculus*) might be a distinct species. The taxon *P. nanus* clearly needs revision. Subspecies: seven of uncertain status. Chromosome number (Zimbabwe, South Africa): $2n = 36$; $aFN = 50$ (Peterson & Nagorsen 1975, Rautenbach *et al.* 1993, Kearney *et al.* 2002).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (7–13 mm); FA: 25–35 mm; dorsal pelage dark; dorsal and ventral hairs bicoloured; wings dark without white hind-border; lower molars nyctalodont, inner upper incisor bicuspid; profile of forehead region of skull strongly concave; posterior margin of tragus sharply angular; usually no glands on interfemoral membrane. Sexes similar in colour; ♀ on average larger than ♂. Pelage soft, dense, fairly fluffy, with silky sheen; mid-dorsal hairs ca. 5 mm. Dorsal pelage chocolate brown or sepia brown, usually with golden sheen; hairs bicoloured, basal half blackish-brown, terminal half chocolate or sepia brown usually merging into golden-brown towards tip. Ventral pelage dark greyish-buff; hairs bicoloured, blackish-brown with greyish-buff at tip. Ears blackish-brown, relatively short, subtriangular; tip rounded; outer margin with lobule at base inconspicuous or absent. Tragus length ca. half E; broadest well above mid-height; hatchet-shaped (anterior margin slightly to distinctly concave, posterior margin making an obtuse-angle bend just above mid-height; no basal lobe); tip narrow and rounded (Figure 136b). Wings blackish-brown; no white hind-border. Thumb very small with friction pad on wrist. Hindfeet very small with friction pad on sole. Interfemoral membrane blackish-brown; sometimes with the posterior margin pale or white. No glands on interfemoral membranes of specimens from Kenya and DR Congo (cf. *P. cf. helios*), but 13 of 93 specimens from Malawi and South Africa had one, rarely two, small opaque disks of unknown significance, usually near the body. Baculum as in Figure 139g (Hill & Harrison 1987).

Skull small and gracile for an African *Pipistrellus*. Braincase on average relatively high and of medium relative breadth (but very variable); interorbital region of medium relative breadth; rostrum on average relatively short and narrow (but again very variable) (Table 25, p. 603). Profile of forehead region (viewed laterally) strongly concave (Figure 137a). No occipital helmet. Inner upper incisor usually bicuspid, sometimes unicuspid. Outer upper incisor at least half height of inner upper incisor (often reaching posterior cusp of inner incisor). Anterior upper premolar medium-sized, somewhat displaced lingually; canine and posterior premolar not in contact. Lower molars nyctalodont. The lower molars of holotypes of *nanus* and *culex* are very worn and some are missing, but they appear to be nyctalodont; those of lectotype of *africanus* are nyctalodont. Dental formula: $2^{123}/_{3123} = 34$.

Geographic Variation The following subspecies of *P. nanus* (as *P. africanus*) were recognized by Koopman (1994) and/or Kock (2001c), but their status and geographic ranges are uncertain (see Taxonomy):

P. n. stampflii: Sierra Leone to Côte d'Ivoire.

P. n. culex: Nigeria, Ghana.

P. n. africanus: DR Congo to Ethiopia, mostly in highlands.

P. n. nanus: DR Congo, Kenya and Tanzania to South Africa, also Cameroon (Rosevear 1965).

P. n. fouriei: S Angola, W Zambia, N Namibia.

P. n. meesteri: Transkei, South Africa.

P. n. minusculus: Liberia.

The subspecific assignment of specimens from C and S Sudan and S Somalia is uncertain. Rosevear (1965) found a clinal increase in size from Sierra Leone to Cameroon and was unable to find lines of demarcation between the subspecies *stampflii*, *culex* and *nanus*. No subspecies were recognized by Hayman & Hill (1971).

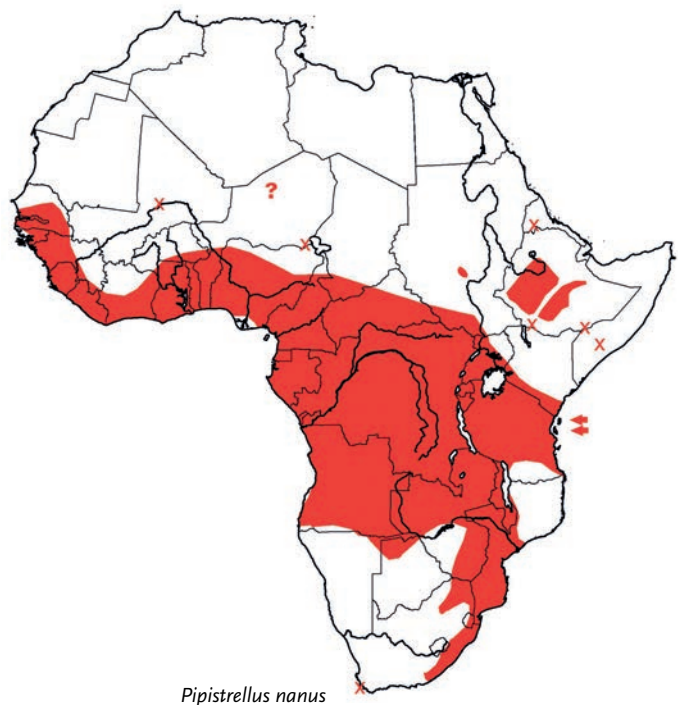

Similar Species Three other sub-Saharan *Pipistrellus* have nyctalodont lower molars and bicuspid inner upper incisors (Table 27, p. 608):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

P. permixtus. Tragus sickle-shaped (posterior margin without abrupt angle).

P. nanulus. Dorsal pelage reddish-brown; hairs unicoloured. Tragus not hatchet-shaped (no abrupt angle on posterior margin). Forearm not known to exceed 29 mm.

Distribution Endemic to Africa. Very widespread in most sub-Saharan biotic zones (except in the South-West Arid and South-West Cape BZs and in the Horn of Africa) but possibly only where banana plants and/or other musaceous plants are found (see Habitat). There are records at oases in Niger (at Air and just south of Air at Tchin-n-Tajet kori) which have not been confirmed (see question mark on map).

Pipistrellus nanus

Habitat Diverse forest and savanna habitats and sometimes sub-desert steppe; sea level to 2500 m. Possibly dependent on musaceous plants for roosts and restricted to habitats moist and warm enough for these plants to grow, either wild or cultivated. There are records in habitats devoid of musaceous plants, but some of these refer to *P. cf. helios* and others possibly refer to cryptic species (see Taxonomy).

Abundance Apparently common wherever banana plants are abundant. On any single day during a ten-month study with sampling at fortnightly intervals, 27–49 individuals roosted by day in a 40×50 m plantation of bananas in Malawi (Happold & Happold 1996).

Adaptations Aspect ratio low; wing-loading very low; flight slow and highly manoeuvrable in confined spaces, faster and very agile in open spaces. Turns by banking (minimum radius <25 cm) and by stalling-and-twisting; can take off from ground; cannot hover; individuals sustained flight in a 1×1×1 m enclosure for up to 23 circuits/flight (10 bats, 10 flights each). Cursorial locomotion on ground, and climbing on sloping surfaces, are moderately efficient; friction pads on wrists and hindfeet facilitate climbing on banana leaves.

Roosts by day in furled leaves of domestic banana and plantain plants *Musa* spp., wild bananas *Ensete* and strelitzias *Strelitzia nicolai* (Musaceae) (e.g. LaVal & LaVal 1977, Baagøe 1978, Happold & Happold 1990b, 1996). Occasionally recorded roosting elsewhere, including in bunches of banana fruits, skirts of dead banana leaves, crevices in thatch, under rafters, in culverts and in a cave (e.g. Fenton *et al.* 1977, LaVal & LaVal 1977, Baagøe 1978, O'Shea & Vaughan 1980), but at least some of these records refer to other species (e.g. *P. cf. helios*). *Ensete* and *Strelitzia* are indigenous to Africa, and bananas were introduced to West Africa 2500 years ago, and to East Africa at least 1000 years ago (Coghlan 2001): consequently, the leaf-roosting form has had time to specialize and adapt to the peculiarities of this roost. It has very little inter-specific competition for roosts – only *Myotis bocagii*, *M. scotti* (and very rarely *M. welwitschii*) sometimes roost in furled leaves in some localities. Furled leaves are only occupied by *P. nanus* if the entrance diameter is 7–24 cm (optimally 19–24 cm). Banana leaves unfurl rapidly and are suitable for only 1–3 days, but they are produced throughout the year. Roost-fidelity (*sensu stricto*) is not possible, but almost half of the ♂♂ in one study showed fidelity to a small number (<5) of clumps of 'reliable' plants growing close together, which invariably had one or more suitable leaves at all times (Happold & Happold 1996). Females did not show such fidelity and their roost-ranges were much larger. In localities where separate banana plantations may be one or more kilometres apart, some individuals apparently maintain at least two separate roost-ranges and alternate between them.

Temperatures inside and outside leaves are similar, but relative humidities inside are 80–100%, even when as low as 35% outside. During the cool dry season, all individuals become torpid during the day; in the hot wet season, only some do. In Malawi, *P. nanus* occurs at some localities where night temperatures are sometimes too low for flying insects to be active, and perhaps the ability to reduce urinary water loss enables these bats to remain torpid for several days at such times. The kidneys have a long papilla and thick medulla; the predicted mean maximum urine concentration is comparatively high (4004 mOsmol/kg) (Happold & Happold 1988). Nevertheless, captives, fed winged termites and offered water twice daily, took 1–2 drinks/day.

Foraging and Food In Malawi, forages by slow-hawking in moderately uncluttered places such as clearings, gaps between trees, and around canopies of trees. Foraging is characterized by acrobatic swerving as small insects are pursued. Foraging begins at dusk and individuals do not return to their furled leaves until just before sunrise, but bouts of foraging appear to be interspersed with periods of inactivity. Small beetles and moths appear to be main components of the diet, with some Diptera also (Fenton & Thomas 1980).

Echolocation Search-phase call-shape (Malawi) steep FM/QCF (Figure 118b). Intensity high; start-frequency up to 111 kHz; end-frequency and peak-frequency 59–67 kHz (usually 63–65 kHz); call-duration 2.5–6.0 ms (depending on duration of the QCF 'heel') (24 bats, foraging, 300 calls; M. Happold unpubl.). Calls with similar end-frequencies were recorded in Zimbabwe (62 kHz, 3 bats, flying in open; Fenton & Bell 1981) and South Africa (67.4 ± 1.4 kHz, 1 bat, flying in open, 4 calls; Taylor 1999a). Taylor also recorded end-frequencies of 42.4 kHz (1 bat, 2 calls), but this bat is not likely to represent *P. nanus*.

Social and Reproductive Behaviour Frequently aggregates to forage, but the composition of aggregations is not known. LaVal & LaVal (1977) observed that in leaf-roosting *P. nanus* in South Africa, adult ♂♂ roost singly or in labile groups comprised of 1–6 adult ♂♂ and 1–8 adult ♀♀ without young, and that adult ♀♀ with young roosted singly or with up to nine other adult ♀♀ with their young. About one-third of 101 banded bats were recaptured at least once, indicating that some are comparatively sedentary.

To obtain further information, the social organization of *P. nanus* roosting in a banana plantation containing 138 clumps of banana plants arranged in a 40×50 m grid was studied by Happold & Happold (1996) in Malawi. Roosting behaviour was fairly similar in both localities – during parturition and lactation, ♀♀ with young roosted separately from ♂♂, and ♂♂ roosted singly. At other times, adult ♂♂ roosted singly, or in groups comprised of one (very rarely two) ♂♂ and 1–10 ♀♀. Formation of groups is not attributable to shortage of leaves. There were invariably more habitable clumps of banana plants (i.e. with two or more suitable leaves) than adult ♂♂, so competition for clumps by ♂♂ was unlikely. On most occasions, each ♂ was found with a different group of ♀♀, and each ♀ with a different ♂, showing that group-membership is highly labile and suggesting that the mating system is promiscuous. Some ♂♂ attracted more ♀♀ than others, but what makes a ♂ attractive to ♀♀, especially during the mating season, is not understood. Males were not heard vocalizing to attract ♀♀ to their roosts (cf. *P. cf. helios*). Bats do not return to their roosts before dawn, there is no evidence that ♂♂ are territorial and they did not have injuries attributable to fighting (cf. *P. cf. helios*). It might be that ♂♂ are selected for the quality of the clumps of banana plants that they roost in, although this did not appear to be the case. Alternatively, each ♀ might mate with many ♂♂ and rely on sperm competition to obtain the best sire for her progeny.

LaVal & LaVal (1977) recorded what appeared to be a maternity colony of 150 bats roosting tightly grouped in a thatched roof in Kruger N. P., South Africa. They were identified as *P. nanus*, but this behaviour is different to that of leaf-roosting *P. nanus*, suggesting that this record refers to a cryptic species or perhaps *P. cf. helios*.

Reproduction and Population Structure Litter-size (Zimbabwe, Malawi, Zambia): invariably two. Elsewhere, embryo counts are rare, but ♀♀ with one or two young have been recorded from South Africa, Namibia, DR Congo, Gabon, Ghana and Liberia: however, ♀♀ with only one young might have given birth to twins and subsequently lost one. There appear to be no records of ♀♀ with single embryos, but 'no cases of twin births' were reported from DR Congo (Verschuren 1966) and Rwanda (Verschuren 1965a). The reproductive chronology in Malawi (15–16°S) is restricted seasonal monoestry, with spermatogenesis in hot wet season (Feb–Apr), mating in cool dry season (mid-Jun to early Jul), sperm storage by the ♀♀ until ovulation in Aug, sperm storage in the ♂ until at least Sep, parturition in mid-Nov ca. 10 weeks after fertilization and 20 weeks after copulation (Bernard *et al.* 1997). This chronology ensures that both spermatogenesis and lactation occur during the hot wet season when insects are maximally abundant. In South Africa, the chronology is also restricted seasonal monoestry (LaVal & LaVal 1977) but, at 25°S, frequent copulations occur between May and beginning of Aug when ovulation and fertilization occur, and there is not strong evidence to support sperm storage at this locality (Stirnermann & van der Merwe 2005). In DR Congo, Gabon and Rwanda, parturition is aseasonal (Lang & Chapin 1917a, Verschuren 1957, 1966, Brosset 1966) but it is not possible to tell, from the available data, whether the chronology is aseasonal monoestry with highly unsynchronized parturition, or aseasonal polyoestry. Furthermore, these data possibly include records from cryptic species.

Neonates are naked, eyes closed, weight ca. 1 g (M. Happold unpubl.). They cling tenaciously to the nipples and to the ventral pelage; they are enclosed by the mother's wings when she rests, and carried when she flies. Neonates groom themselves with rapid combing movements of the hindfeet. Detached neonates make vocalizations (audible to humans) but do not appear to echolocate. By week 3, cursorial scuttling over horizontal and sloping surfaces is efficient, and they echolocate. By week 7, deciduous dentition begins to be replaced. By week 9, the diet includes insects as well as milk and the young are just volant. Weaning occurs at 8–9 weeks.

Sex ratio at birth is 1 : 1. In the banana plantation in Malawi, adult ♂♂ were outnumbered by adult ♀♀ (1 : 1.7) during the hot wet season when ♀♀ were pregnant, but more ♀♀ were lost during the wet season, when they were lactating and post-lactating, and the ratio reversed (1 : 0.8). Seasonal fluctuations in the sex ratio possibly explain the differently biased sex ratios reported for DR Congo and Senegal by Verschuren (1957, 1966, 1982).

Predators, Parasites and Diseases Predators include Bat Hawks *Macheiramphus alcinus* (Lang & Chapin 1917a). A Grey-headed Bush-shrike *Malaconotus blanchoti* was observed opening furred banana leaves and, on one occasion, removing a bat (Van Jaarsveld 1988). Ectoparasites include a bed-bug *Cacodmus villosus* (Hemiptera: Cimicidae); bat-flies *Nycteribia schmidli*, *N. styliidiopsis*, *Basilia daganiae*, *B. ansifera*, *B. robusta*, *B. tarda* (Diptera: Nycteribiidae); a tick *Carios vespertilionis* (Acari: Argasidae); and mites *Spinturnix walkerae*, *Meristaspis kenyaensis* (Acari: Spinturnicidae), *Chelanyssus aethiopicus*, *Steatonyssus eos*, *S. brucei*, *S. afer* (Acari: Macronyssidae), *Acanthophthirus radfordi* (Acari: Myobiidae), *Alabidocarpus eptesicus* (Acari: Chirodiscidae), *Notoedres miniopteri* (Acari: Sarcopidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Because it roosts in banana leaves, this is one of the few species that benefit from the conversion of natural habitats to subsistence farms and villages.

Pipistrellus permixtus DAR-ES-SALAAM PIPISTRELLE

Fr. Pipistrelle de Tanzanie; Ger. Verwechselte Zwergfledermaus

Pipistrellus permixtus Aellen, 1957. Rev. Suisse Zool. 64: 200. Dar-es-Salaam, Tanzania.

Taxonomy Traditionally *Pipistrellus permixtus*. Subsequently classified as *P. (Pipistrellus) permixtus* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005). According to Aellen (1957), *Pipistrellus permixtus* is more closely related to Palearctic or Oriental members of the genus such as *P. pipistrellus* and *P. nathusii* (Keyserling & Blasius, 1839) than to the other African pipistrelles. Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (ca. 13 mm); FA: ca. 34 mm; dorsal hairs bicoloured; lower molars nyctalodont, inner upper incisor bicuspid; profile of forehead region of skull moderately concave; posterior margin of tragus smoothly convex.

Only known from holotype. Sexual dimorphism: no information. Dorsal pelage colour not known (colour lost before species was described [Aellen 1957]); hairs bicoloured. Pelage extending on to proximal fifth of interfemoral membrane on the dorsal side. Ventral pelage not pure white (no other information). Ears relatively short; tip rounded. Tragus length ca. one-third of E; broadest just above middle of anterior margin; sickle-shaped (anterior margin concave, posterior margin smoothly convex; tip rounded). Wing-membrane: no information. Thumb relatively long. Tail not projecting beyond interfemoral membrane. Postcalcaneal lobe large, well developed. Bacular morphology not known.

Skull medium-sized for an African *Pipistrellus*. Supraorbital region not so expanded that the dorsal surface of the rostrum assumes a pentagonal outline (cf. *P. eisenrauti*). Profile of forehead region (viewed laterally) moderately concave. Inner upper incisor bicuspid. Outer upper incisor about two-thirds height of inner incisor (i.e. as high as the posterior cusp of the inner incisor). Anterior upper premolar well developed and clearly visible above gum; displaced lingually according to Aellen (1957) although Koopman (1994) found it to be in the toothrow. Lower canines relatively robust. Lower molars nyctalodont (Menu 1987). Dental formula: $\frac{2123}{3123} = 34$.

Geographic Variation No information.

Similar Species Three other sub-Saharan *Pipistrellus* have nyctalodont lower molars and bicuspid inner upper incisors (Table 27, p. 608):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

P. nanulus. Dorsal hairs unicoloured. No known overlap in distribution.

P. nanus. Tragus hatchet-shaped (posterior margin with abrupt angle).

Distribution Known only from Dar-es-Salaam in Tanzania. Because this bat appears to be related to Palaearctic pipistrelles, Kingdon (1974) suggests that it might have come to the port of Dar-es-Salaam as a stowaway.

Remarks Nothing more is known about the biology of this bat.

Conservation IUCN Category: Data Deficient.

Pipistrellus pipistrellus COMMON PIPISTRELLE

Fr. Pipistrelle commune; Ger. Zwergfledermaus

Pipistrellus pipistrellus (Schreber, 1774). Die Säugethiere 1: 167. France.

Taxonomy Originally *Vespertilio pipistrellus*. Traditionally *Pipistrellus pipistrellus*. Subsequently classified as *Pipistrellus pipistrellus* by Menu (1987), and as *P. (Pipistrellus) pipistrellus* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005). Synonyms: none in Africa. Does not include *Pipistrellus hanaki*, a recently discovered cryptic species (see profile) distinguished by differences in its echolocation and genetic (DNA) characteristics (Benda *et al.* 2004b, Hulva *et al.* 2004). Subspecies: meristic and genetic information

support that *P. pipistrellus*, the 45 kHz phonic type, occurs in North Africa but it should represent a distinct subspecies (Barratt *et al.* 1995, 1997). Chromosome number (Europe): 2n = 44; aFN = 50 as in all European *Pipistrellus* spp. (Volleth *et al.* 2001).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two

upper incisors on each side; ears separated and short (7–11 mm); FA: 28–33 mm; wings dark, sometimes with pale hind-border; dorsal pelage pale brownish to greyish-brown; dorsal and ventral hairs bicoloured; lower molars nyctalodont; inner upper incisor bicuspid; profile of forehead region of skull moderately concave; posterior margin of tragus without sharp angle. The smallest bat in North Africa. Sexes similar. Pelage dense, soft; mid-dorsal hairs ca. 5 mm. Dorsal pelage pale brownish to greyish-brown; hairs distinctly bicoloured with basal two-thirds to three-quarters dark brown. Ventral pelage paler; hairs with basal two-thirds to three-quarters dark brown. Naked skin of muzzle and around eyes dark brown. Ears dark brown, subtriangular with rounded tip. Tragus length ca. half of E; widest at mid-height; anterior margin slightly concave; posterior margin smoothly convex; tip rounded. Wing and interfemoral membranes dark brown; wings usually without a hind-border but sometimes with a pale hind-border. Penis typically very pale grey (almost unpigmented) with a long, pale median band on dorsal side of glans penis (cf. *P. hanaki*). Baculum long, thin, bifurcated at both ends, ca. 1.8 mm long (Figure 139h; Benda *et al.* 2004b).

Skull small and gracile for an African *Pipistrellus*. Braincase relatively narrow; interorbital region of medium relative breadth; rostrum relatively short and narrow (Table 25, p. 603). In European specimens, the braincase is relatively high (no data for African specimens). Profile of forehead region (viewed laterally) moderately concave. Occipital helmet almost absent; sagittal crest almost absent. Inner upper incisor bicuspid (posterior cusp ca. two-thirds height of main cusp). Outer upper incisor almost as high as inner incisor. Canines comparatively weak (cf. *P. hanaki*). Anterior upper premolar present, visible above gum, slightly displaced lingually; canine and posterior premolar not in contact. Lower molars nyctalodont. Dental formula: $\frac{2^{123}}{3^{123}} = 34$.

Geographic Variation None in Africa (Benda *et al.* 2004b).

Similar Species Seven other *Eptesicus* and *Pipistrellus* occur in North Africa (excluding *P. ariel* in S Egypt):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

P. hanaki. Forearm on average larger (32.4 [31–33] mm). Skull longer (GLS: 12.4 [12.1–12.7] mm). Dorsal pelage paler and with rusty tinge. NE Libya (Cyrenaica).

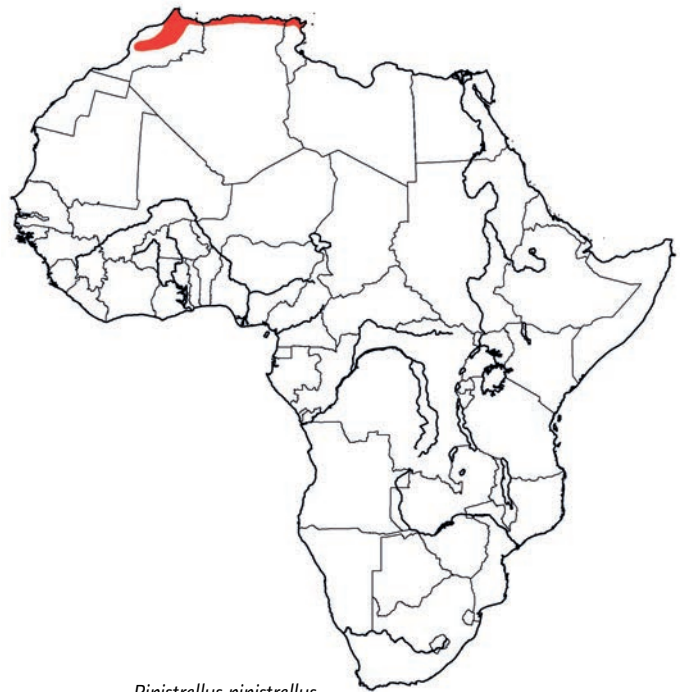

P. kuhlii. Wings with white hind-border. Inner upper incisor unicuspid. Outer upper incisor much smaller than inner incisor.

P. deserti. Wings with white hind-border. Inner upper incisor unicuspid.

P. savii. Larger (FA: 34–38 mm; GLS: 12.8–14.6 mm). Dorsal hairs conspicuously bicoloured. Anterior upper premolar minute, not visible above gum, sometimes absent. Lower molars myotodont.

Eptesicus (2 spp.). Larger (FA: 38–52 mm; GLS: 15.3–20.1 mm). Anterior upper premolar always absent.

Distribution In Africa, only known from mountainous areas in the Mediterranean Coastal and Afromontane–Afroalpine BZs of NW Africa (the Maghreb). Recorded from Morocco (Rif, Middle Atlas, High Atlas), Algeria (Tell Atlas, Hauts Plateaux and Aures Mts) and Tunisia (Panouse 1951, Vaughan *et al.* 1977, Aulagnier & Thévenot 1986, Kowalski & Rzebiak-Kowalska 1991, Fonderflick *et al.* 1998,

Pipistrellus pipistrellus

Beneš & Hanák 2003, Benda *et al.* 2004d). Extralimitally: widely distributed in Europe (including British Isles and south Scandinavia), Asia Minor to Kashmir and Sinkiang (China).

Habitat In Algeria, specimens have been mist-netted in a park in the town of Setif, over irrigation basins and a permanent stream among orchards, and in forests including Cork Oak *Quercus suber* forests with other broadleaved trees (Gaisler & Kowalski 1986). In N Morocco, recorded in Cedar *Cedrus atlantica* and Green Oak *Q. ilex* forests. Some individuals were also captured near an oasis in a semi-desert environment in the Aures Mts (Gaisler & Kowalski 1986), and on the southern slope of the High Atlas, where vegetation was restricted to rare palm trees *Phoenix dactylifera* along rivers running through rocks and cliffs (Fonderflick *et al.* 1998). Recorded up to 2650 m (Benda *et al.* 2004d).

Abundance Common (in mountainous areas). In Algeria, the most frequently captured species during mist-netting sessions in Tlemcen and Djurdjura Mts; abundance decreases toward the coastal zone where *P. kuhlii* is more abundant.

Adaptations Aspect ratio low to very low (Great Britain; Jones & Van Parijs 1993); wing-loading not known. Flight-speeds of 4.3 m/sec (Baagoe 1987) and 4.5 m/sec (Jones & Rayner 1989b) have been recorded. By day, roosts mainly in buildings, ruins and also in trees (Morales Agacino 1933, Brosset 1960a, Gaisler 1983, Benda *et al.* 2004d); probably also roosts in caves and mines as it was mist-netted at the entrance of an abandoned lead mine in Tunisia (Vaughan *et al.* 1977). In Europe, most populations are sedentary but some large movements have been recorded in Germany (up to 770 km; Schöber & Grimmberger 1987). In Algeria, activity decreases from Dec–Feb when some time is probably spent in hibernation, but one individual was mist-netted in Jan when temperature was 6.5 °C, although no other bats were observed (Gaisler 1984).

Foraging and Food Forages by slow-hawking in various habitats including fields, steppes and forests. Usually emerges early in evening and is most active during first half of night (Gaisler & Kowalski 1986). Diet in Africa not known. In Switzerland and Britain, feeds on small insects, mainly Diptera, and also Lepidoptera and Hemiptera (Beck 1995, Barlow 1997).

Echolocation Search-phase call-shape (2–5 m from obstacles) steep FM/QCF. Start-frequency ca. 70–85 kHz; end-frequency (QCF component) 44–48 kHz; call-duration 5–7 ms (Tupinier 1996); inter-call interval 82.3 ± 10.5 ms (Jones & Van Parijs 1993). When flying in clutter, uses only steep linear FM calls (Jones & Van Parijs 1993).

Social and Reproductive Behaviour Usually roosts in groups (colonies). In Europe, ♀♀ begin to establish maternity colonies in Apr–May and leave them in early Aug, at least 15–20 days before their young leave them. Maternity colonies contain 20–200 ♀♀ and subadults (Barlow & Jones 1999). Males establish individually occupied territories from late Aug to late Sep, vocalizing and emitting a strong smell during display flights close to the roosts where mating occurs (Schober & Grimmberger 1987); they have harems of 2–3 ♀♀ (Park *et al.* 1996). In winter they roost either isolated or in clusters up to 2000 individuals (and even 100,000 in one Romanian cave; Decu *et al.* 2003).

Reproduction and Population Structure Litter-size: one in SW Europe, two in NE Europe. In Europe, the reproductive chronology is restricted seasonal monoestry with parturition from mid-Jun to early Jul; young become volant when 3–4 weeks old (Schober & Grimmberger 1987). In Algeria, one ♀ with one embryo was recorded in early Jun (Gaisler 1983). Maximum longevity: 16 years and 7 months (Schober & Grimmberger 1987).

Predators, Parasites and Diseases Ectoparasites include fleas *Ischnopsyllus intermedius*, *I. octactenus* and *Nycteridopsylla longiceps* (Siphonaptera; Ischnopsyllidae) (Anciaux de Faveaux 1976, Beaucournu & Kowalski 1985).

Conservation IUCN Category: Least Concern (based largely on extralimital data).

Measurements

Pipistrellus pipistrellus

Pipistrellus rendalli RENDALL'S PIPISTRELLE

Fr. Pipistrelle de Rendall; Ger. Rendalls Zwergfledermaus

Pipistrellus rendalli (Thomas, 1889). Ann. Mag. Nat. Hist., ser. 6, 3: 362. Bathurst, Gambia.

Taxonomy Originally *Vesperugo* (*Vesperus*) *rendalli*. Traditionally *Eptesicus rendalli*. Subsequently classified as *P.* (*Neoromicia*) *rendalli* by Hill & Harrison (1987) and Koopman (1993, 1994), *Nycterikaupius rendalli* by Menu (1987) and *Neoromicia rendalli* by Kearney *et al.* (2002) and Simmons (2005). Synonyms: *faradjius*, *phasma*. Subspecies: two. Chromosome number (Somalia, Zimbabwe, South Africa): 2n = 38; aFN = 50 (McBee *et al.* 1987, Rautenbach & Fenton 1992, Kearney *et al.* 2002).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and two upper incisors on each side; ears separated and short (8–14 mm); FA: 29–37 mm; dorsal pelage pale; wings white and not contrasting markedly with dorsal pelage; lower molars myotodont, inner upper incisors unicuspid; profile of forehead region of skull straight. Sexes similar in colour; ♀♀ on average with slightly larger body measurements. Pelage fluffy, without sheen; mid-dorsal hairs 5–6 mm. Dorsal pelage pale to medium-pale brown, not

strongly contrasting with colour of wings; hairs fawn with dark brown at base (sometimes reddish at tip) or with basal third dark greyish-brown, middle third beige, terminal third fawn. Ventral pelage cream, whitish or pale grey (flanks and anal region sometimes pure white); hairs with basal half dark greyish-brown, or pure white. Ears pale brown, subtriangular; tip rounded. Tragus length ca. half of E; broadest above mid-height; anterior margin straight for most of its length (slightly concave near tip); posterior margin smoothly convex with triangular basal lobe; tip rounded (Figure 136m). Wings and interfemoral membrane creamy-white; skin over bones brownish-pink; venation lines cream. Wing-membranes translucent. Interfemoral membrane more heavily pigmented; tail completely enclosed by membrane; postcalcarea lobe present. Baculum as in Figure 141g (Hill & Harrison 1987).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region of medium breadth; rostrum relatively short but of medium relative breadth (Table 25, p. 603). Profile of forehead region (viewed laterally) straight. Occipital helmet present but low.

Inner upper incisor unicuspid with small basal cusp (not always visible). Outer upper incisor half height of inner incisor; triangular in transverse section and sometimes with a small basal cusp at one or both angles. Anterior upper premolar absent. Lower molars myotodont. Dental formula $\frac{2^{113}}{3123} = 32$.

Geographic Variation Two subspecies are recognized by Koopman (1994) and Simmons (2005), but considered dubious by Kock *et al.* (2002):

P. r. rendalli: Gambia to Chad.

P. r. phasma: Sudan and Somalia to Botswana and Mozambique.

Ansell (1978) and Ansell & Dowsett (1988) indicate that the southern populations of *Pipistrellus rendalli* have a shorter tail and longer ears than populations from other parts of the distribution, but this is incorrect (see Kock *et al.* 2002 for details).

Similar Species Three other African vespertilionids have white wings:

Pipistrellus tenuipinnis. Dorsal pelage blackish-brown, contrasting conspicuously with the white wings. Sometimes smaller (FA: 29.8 [28–33] mm). Inner upper incisor weakly bicuspid. Mostly in wetter habitats.

Scotoecus albobfuscus. Only one upper incisor on each side; penis very long.

Glauconycteris gleni. Dark brown pigment over wing-bones; brown reticulation lines on arm-wing. Outer margin of ear reaching mouth. Lower lip with lobe at posterior corner.

Distribution Endemic to Africa. Widespread in most biotic zones and mosaics south of the Sahara, but recorded only marginally in the Rainforest BZ and not recorded from the Sahel Savanna, South-West

Arid and South-West Cape BZs, nor from the Horn of Africa. Recorded disjunctly, and not in all countries, from Senegal to Sudan and Somalia and southwards to Mozambique, Botswana and E South Africa.

Habitat Mainly woodland savannas from West Africa to Sudan and Somalia, but also degraded lowland rainforest habitats on border of rainforest zone. Known altitudinal range: sea level (Tanga, Tanzania) to 1480 m (Katana, DR Congo). In Mali, frequently reported over ditches and small ponds (Meinig 2000) and, in Burkina, netted over the Mékrou R. and Niger R. (Poché 1975). In Abuko N. P., Gambia, recorded flying over permanent freshwater pools within gallery forests (Kock *et al.* 2002). In Malawi, recorded over a swamp in the Lower Shire Valley. In southern Africa, recorded from well-watered habitats including Mana Pools in Zimbabwe, the Okavango Swamp in Botswana, and a pan within the Zululand Palm Veld in KwaZulu-Natal, South Africa (Kearney & Taylor 1997).

Abundance Not often recorded and considered to be rare throughout range (Smithers 1983, Happold & Happold 1997), but possibly not uncommon in some localities (Rosevear 1965).

Adaptations Aspect ratio low; wing-loading low. Flight slow with bursts of speed; manoeuvrability poor; turns by banking (minimum radius of turn >50 cm) and by stalling-and-twisting. Able to fly across a 1×1×1 m enclosure, but not able to complete a full circuit (3 bats, 10 flights each; M. Happold unpubl.). Wings make distinct whirring noise during flight (Lang & Chapin 1917b). Roosts by day in dense foliage of low bushes and trees, and in huts and houses (especially after dry-season fires when bushes and trees are leafless) (Lang & Chapin 1917b). In Faradje, DR Congo, 'they clung to the brick walls or to the rafters or even to a single grass stalk hanging from the thatch' and preferred the more secluded and darker places (Lang & Chapin 1917b). When disturbed, they moved quickly out of sight, climbing over the brick walls or deeper into the recesses of the thatch. Also recorded roosting among leaves of *Hyphaene* palms in Sudan (BMNH) and S Malawi (Thomas 1896), and in a cotton plant (R. C. Wood, field notes in Kershaw 1922). Does not become torpid during day in DR Congo (Lang & Chapin 1917b). In S Mali, observed drinking from ditches and small ponds shortly after dawn (Meinig 2000).

Foraging and Food Forages for small insects by slow-hawking, usually within 2 m of the ground (Lang & Chapin 1917b). Foraging begins early in the evening. Sometimes forages in vicinity of houses, but rarely enters lighted houses. Also forages low over swamps, pools, pans and rivers (Taylor, P. 1998, M. Happold unpubl.). In Kenya, stomach contents (n = 9) in dry season contained mainly moths, beetles and bugs, with some Orthoptera and other insects (Whitaker & Mumford 1978).

Echolocation Search-phase call-shapes (Malawi): include CF, shallow linear FM and steep/shallow FM. Intensity high; start-frequency up to 76 kHz; end-frequency 42–44 kHz (four tethered bats and others foraging; M. Happold unpubl.).

Social and Reproductive Behaviour Observed roosting in groups of up to six individuals (Lang & Chapin 1917b).

Pipistrellus rendalli

Reproduction and Population Structure Litter-size: 2 (n = 1). Reproductive chronology not known. The record of one ♀ simultaneously lactating and pregnant with two embryos in Dec in KwaZulu–Natal (Taylor, P. 1998), suggests polyoestry with postpartum oestrus, but it is not yet known if polyoestry is normal in this species. At ca. 4°N (Garamba N. P., NE DR Congo), a ♀ with two juveniles was recorded at end of Apr (Verschuren 1957); no data for other months. At ca. 16°S in Malawi, 1 of 2 ♀♀ was lactating and the other post-lactating in Apr: neither was pregnant (M. Happold unpubl.).

Predators, Parasites and Diseases Ectoparasites include bed-bugs *Cacodmus ignotus*, *Aphrania recta* (Hemiptera: Cimicidae) (Ueshima 1968); bat-flies *Basilina ansifera*, *B. bouvieri* (Diptera: Nycteribiidae); and mites *Spinturnix walkerae*, *Spinturnix faini* (Acari: Spinturnicidae); and *Rodhainyssus eptesicus* (Acari: Gastronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.
Widespread; no known threats.

Pipistrellus rueppellii RÜPPEL'S PIPISTRELLE

Fr. Pipistrelle de Rüppell; Ger. Rüppells Zwergfledermaus

Pipistrellus rueppellii (J. Fischer, 1829). Synopsis Mammalium, p. 109. Dongola, Northern Province, Sudan.

Taxonomy Originally *Vespertilio temminckii* Cretzschmar, 1827; renamed *Vespertilio Rüppellii*. Traditionally *Pipistrellus rueppellii*. Subsequently classified as *P. (Pipistrellus) rueppellii* by Hill & Harrison (1987), Koopman (1993) and Simmons (2005), *P. (Vansonia) rueppellii* by Koopman (1994), and *Pipistrellus rueppelli* by Menu (1987). The specific name is sometimes spelled without the first *e* and with *ü*, and/or with one *p*, one *l* or one *i*: of these, *rueppellii* (although not the original spelling) is used most commonly, and is retained here in the interests of stability and because the species is named after Rüppell. Synonyms: *coxi*, *fuscipes*, *hypoleucus*, *leucomelas*, *pulcher*, *senegalensis*, *vernayi*. Subspecies: uncertain (see Geographic Variation). Chromosome number (South Africa): 2n = 36; aFN = 54 (Rautenbach *et al.* 1993).

Description Very small (and very beautiful) microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (6–14 mm); FA: 29–37 mm; lower molars nyctalodont; mid-ventral pelage uniquely pure white (cf. all other African *Pipistrellus*). Sexes similar in colour and size. Pelage soft, dense, sleek; mid-dorsal hairs 5–6 mm. Dorsal pelage grey, pale greyish-brown or sepia brown, sometimes with silvery sheen; hairs dark sepia brown or dark grey with either sepia brown or pale grey at tip. Ventral pelage (except throat) pure white; hairs pure white. Throat pure white or pale rusty-brown. Ears relatively long for this genus; subtriangular, rounded at

tip; outer margin with semi-circular lobule at base. Tragus length ca. half of E; breadth constant for most of length; anterior margin slightly concave; posterior margin slightly and smoothly convex with small lobule at base; tip rounded (Figure 136n). Wings usually translucent pale grey but varying from whitish to medium brown; pale hind-border present in at least some specimens. Interfemoral membrane pale grey. Penis relatively long (12–13 mm). Baculum as in Figure 139i, j (Hill & Harrison 1987); variation in Kearney *et al.* (2002).

Skull medium-sized and moderately robust for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region of medium relative breadth; rostrum of medium relative length but relatively narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave to almost straight. No occipital helmet. Inner upper incisor very long, very deeply bicuspid and grooved. Outer upper incisor small (not more than half height of inner incisor) to minute (ca. same height as cingulum of inner incisor), sometimes tucked close against inner incisor. Anterior upper premolar medium-sized, clearly visible above gum, within tooththrow but sometimes slightly displaced linguallly; canine and posterior premolar not in contact. Lower molars nyctalodont. Dental formula: $^{2123}_{3123} = 34$.

Geographic Variation Five African and one extralimital subspecies are recognized by Koopman (1994), but their validity is uncertain. The African subspecies are:

- P. r. senegalensis*: Algeria to Senegal.
P. r. rueppellii: Egypt to Nigeria and C Sudan.
P. r. fuscipes: Ethiopia to N Angola.
P. r. pulcher: NE Tanzania.
P. r. leucomelas: Malawi to the former Transvaal and S Angola.

In contrast, Smithers (1983), Meester *et al.* (1986) and Simmons (2005) recognize *vernayi* as a subspecies but not *leucomelas*. The status of *leucomelas* is controversial; it is considered a synonym of *P. r. rueppellii* by Meester *et al.* (1986) and a synonym of *P. r. vernayi* by Simmons (2005).

Similar Species No other African *Eptesicus* or *Pipistrellus* has ventral pelage (excluding throat) pure white.

Distribution In Africa, recorded very disjunctly in almost all biotic zones (a notable exception being the Somalia–Masai Bushland BZ), but not widely recorded in any zone except the Eastern Rainforest–Savanna Mosaic. Occurs along the Nile R. and its tributaries in Egypt and Sudan, then Ethiopia to W coast of DR Congo and southwards to Angola, Botswana and extreme N of South Africa; also Zanzibar I. There are seemingly isolated records in NE Nigeria, Chad, Morocco and Algeria, and on the N Senegal–Mauritania border. Furthermore, there is a recent record (not mapped) at 16° 29' 969 N, 07° 42' 911 W in SE Mauritania (Padial & Ibáñez 2005). Extralimittally: Arabia, Israel, Bahrain and Iraq.

Habitat Mainly woodland and grassland savannas, but occasionally found in desert habitats and montane forests and along some river systems in the rainforest zone in DR Congo. In Mauritania, found in Sahel savannas; the most recent record being from 'temporary wetland surrounded by Sahel savannas composed mainly by *Acacia* spp. formations' (Padial & Ibáñez 2005). In Egypt, Zambia, Botswana and Zimbabwe, associated with rivers or swamps (Smithers 1983). In Malawi, common near streams, ponds and lakes in montane

forests. Probably dependent on rivers, lakes or large pools over which to forage. Forest areas are largely avoided according to Koopman (1994), but possibly this only applies to forests without suitable foraging areas over water. Has been recorded from sea level (Tanzania) to 1700 m (Malawi).

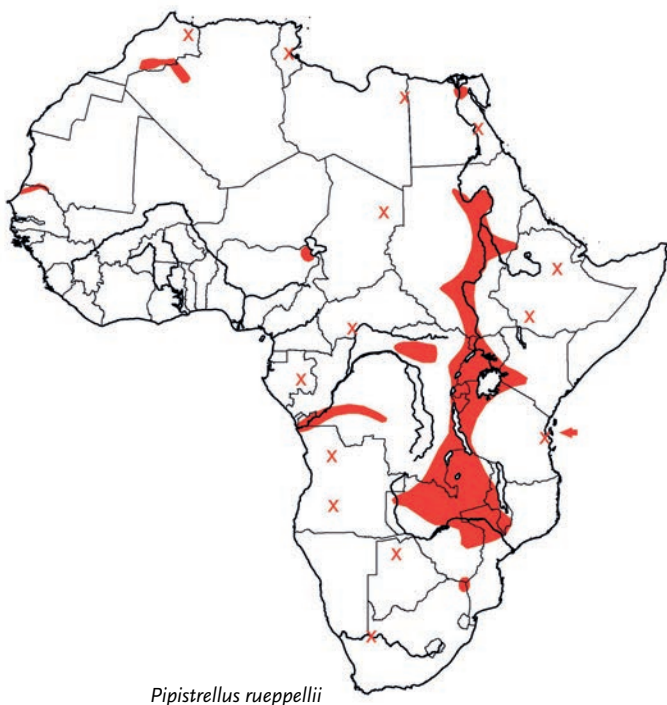

Abundance Uncertain. Moderately common in some localized areas near open water. Rare in Morocco and considered to be a remnant population there (Arlettaz & Aulagnier 1988).

Adaptations Aspect ratio low; wing-loading very low. Flight slow and highly manoeuvrable in confined spaces, faster and very agile in open spaces. Turns by banking (minimum radius <25 cm) and by stalling-and-twisting; can take off from ground; cannot hover. Individuals sustained flight within a 1×1×1 m enclosure for up to three circuits/flight (7 bats, 10 flights each). Cursorial locomotion on ground and climbing on sloping surfaces are moderately efficient. By day, has been found under plaster on the wall of a ruin (Allen & Loveridge 1933), behind a notice board against a wall (Ansell 1960a) and under rocks in desert and semi-desert areas in Egypt (Hoogstraal 1962). In Malawi, individuals sometimes became torpid during the day at 21–24 °C. Kidneys with short papilla; predicted mean maximum urine concentration comparatively low (3045 mOsmol/kg) (Happold & Happold 1988).

Foraging and Food Often (perhaps almost always) forages by slow-hawking over open water and its surrounding grassy or marshy areas. Foraging individuals fly straight and fast with frequent interruptions to swerve, dive or swoop upwards in pursuit of prey – such manoeuvres are very acrobatic (M. Happold unpubl.). They often fly within a metre of the surface, but intermittently fly higher, up to ca. 10 m. They occasionally make contact with water, sometimes up to seven contacts in very quick succession; this might be to obtain water but the frequency of contacts suggests that they probably take prey from the water surface. Foraging has been observed over lakes, dams, ponds, rivers and open stretches along streams (Archer 1977, M. Happold unpubl.). Faecal pellets of one individual contained remains of Coleoptera only (Aldridge & Rautenbach 1987).

Echolocation Search-phase call-shape (Malawi): steep FM/QCF and curvilinear steep/shallow FM (Figure 118f–h). Intensity high; start-frequency up to 100 kHz; end-frequency and peak-frequency 41–48 kHz (usually 46–48 kHz); maximum duration 7.3 ms (eight bats, flying in open; M. Happold unpubl.). In Zimbabwe, call-shape steep-shallow FM; start-frequency 70 kHz; end-frequency 40 kHz; peak-frequency 45 kHz; maximum duration 8 ms (one bat, flying in open; Fenton & Bell 1981). In South Africa, call-shape FM (no details); start-frequency 70 kHz; end-frequency 40 kHz (five bats in flight-cage; Aldridge & Rautenbach 1987).

Social and Reproductive Behaviour Congregates in small numbers (up to several dozens) over water and sometimes individuals follow each other. Found singly or in pairs under rocks in Egypt (Hoogstraal 1962). One was found behind a notice board against a wall, and another in the same place several days later (Ansell 1960a). Sometimes said to be 'solitary' (e.g. Ansell 1960a), but observations are too few to be conclusive.

Reproduction and Population Structure Litter-size and reproductive chronology not known. Juveniles have been reported in Sep and Nov in Zambia (Ansell 1960a, 1986), and very young subadults in Dec in Malawi (Happold & Happold 1990a), but year-round data are not available.

Predators, Parasites and Diseases Ectoparasites include a flea *Ischnopsyllus emminus* (Siphonaptera: Ischnopsyllidae) (Beaucournu & Kock 1996).

Conservation IUCN Category: Least Concern.
Widespread; no known threats.

Pipistrellus rusticus RUSTIC PIPISTRELLE (RUSTY PIPISTRELLE)

Fr. Pipistrelle rustique; Ger. Rustikale Zwergfledermaus

Pipistrellus rusticus (Tomes, 1861). Proc. Zool. Soc. Lond. 1861: 35. 'Damaraland'. Limited to Olifants Vlei, Damaraland, Namibia by Thomas (1926).

Taxonomy Originally *Scotophilus rusticus*. Traditionally *Pipistrellus rusticus*. Subsequently classified as *P. (Pipistrellus) rusticus* by Hill & Harrison (1987), Koopman (1993, 1994) and Simmons (2005), and *Pipistrellus rusticus* by Menu (1987) and Kearney *et al.* (2002). Synonyms: *marrensis*. Subspecies: two. Chromosome number (South Africa): 2n = 42; aFN = 50 (Rautenbach *et al.* 1993). This species shares the Robertsonian fusion chromosome 11/12 with *P. hesperidus* (Kearney *et al.* 2002).

Description Very small microbat without noseleaf, tail more or less fully enclosed in interfemoral membrane; five upper cheekteeth (all visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (10–12 mm); FA: 24–31 mm; wings dark, sometimes with white hind-border; dorsal pelage variable; dorsal and ventral hairs bicoloured; lower molars nyctalodont; inner upper incisor unicuspid; profile of forehead region of skull straight to weakly concave; posterior margin of tragus without sharp angle. Sexes similar. Pelage soft, dense; mid-dorsal hairs ca. 4 mm. Dorsal pelage reddish-brown, orange-brown, greyish-orange, greyish-brown or medium brown; hairs with basal half medium brown, dark brown or blackish-brown. Both paler and darker individuals are sometimes found at the same localities. Ventral pelage orange, yellowish-orange, creamy-orange, yellow, or cream; darkest under chin, palest in pelvic region; hairs with basal half blackish-brown. Naked skin on muzzle and around eyes pale or medium brown. Ears pale or medium reddish-brown, triangular with rounded tip. Tragus length just under half of E; widest near mid-height, anterior margin straight; posterior margin smoothly convex for most of its length but with wide, deep notch above a basal lobe at base; tip rounded (Figure 136o). Wing-membranes pale brown, dark brown or reddish-black; sometimes

with narrow white hind-border. Interfemoral membrane medium brown or reddish-brown, paler than wing-membranes; sometimes with cream border. Baculum as in Figure 139k, l (Hill & Harrison 1987, Kearney *et al.* 2002).

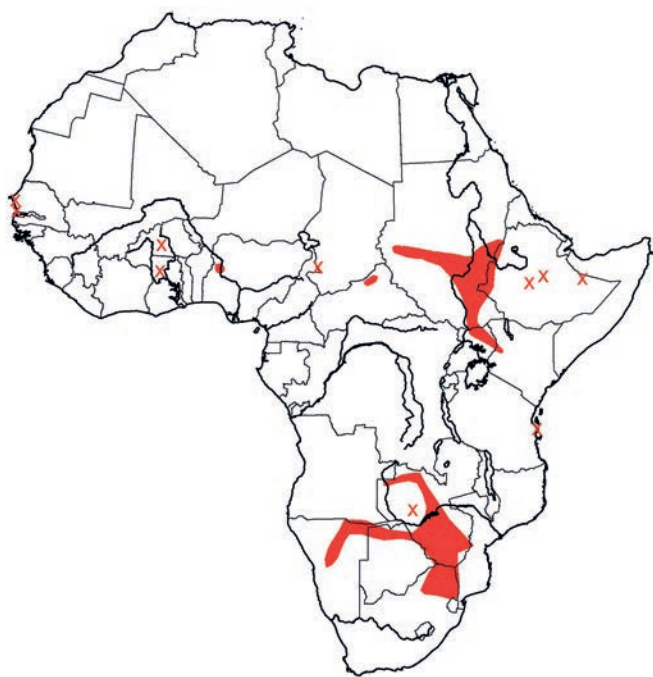

Skull small and gracile for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region of medium relative breadth; rostrum of medium relative length but relatively broad (Table 25, p. 603). Profile of forehead region (viewed laterally) straight to weakly concave. No occipital helmet. Inner upper incisor unicuspid. Outer upper incisor minute, reaching only slightly above cingulum of inner incisor. Anterior upper premolar usually present, minute, seldom visible above gum, displaced lingually; canine and posterior premolar in contact. Lower molars nyctalodont. Dental formula: $2^{123}/_{3123} = 34$.

Geographic Variation Two subspecies are recognized (Koopman 1994, Simmons 2005):

P. r. marrensis: Senegal to Ethiopia and NW Kenya. On average slightly smaller (FA: 26.8 [25–31] mm, n = 39; GLS: 11.3 [10.8–12.3] mm, n = 25; C–M³: 4.0 [3.6–4.4] mm, n = 26; V. Van Cakenberghe pers. comm.). Skull with narrower rostrum.

P. r. rusticus: Zambia, NE Namibia, N Botswana, Zimbabwe and NE South Africa. On average slightly larger (FA: 27.8 [24–31] mm, n = 58; GLS: 11.7 [11.0–12.6] mm, n = 43; C–M³: 4.2 [3.8–4.6] mm, n = 43; V. Van Cakenberghe pers. comm.). Skull with broader rostrum.

Similar Species Three other sub-Saharan *Pipistrellus* have lower molars nyctalodont; inner upper incisors unicuspid (Table 27, p. 608):

*Pipistrellus rusticus*

Pipistrellus aero. Dorsal pelage dark brown. Forearm usually longer (31–34 mm). Profile of forehead region of skull moderately concave. Kenya, Ethiopia.

P. deserti. Dorsal pelage pale sepia brown to pale yellowish-brown (sometimes with greenish tint). Wings with white hind-border. Profile of forehead region of skull moderately concave. Distribution possibly only overlapping in West Africa, Sudan and Kenya.

P. hesperidus. Dorsal pelage darker, less orange and longer. Wings without white hind-border.

Distribution Endemic to Africa. Distribution disjunct. Recorded from scattered localities in the Sudan Savanna, Guinea Savanna and Somalia–Masai Bushland BZs, from Senegal and Gambia to Ethiopia (but not in all countries). A record from Niumi N. P., Sine Saloum Delta in Gambia (13° 35'N, 16° 32'W) by Kock *et al.* (2002) is not mapped. Also recorded from one locality in the Coastal Forest Mosaic BZ in E Tanzania, and from several localities in the Zambezian Woodland BZ and northern fringe of the South-West Arid BZ. The southern records are from W Zambia, Namibia, N Botswana, Zimbabwe and South Africa. The occurrence of *P. rusticus* in Malawi is uncertain (M. Happold & V. Van Cakenberghe pers. comm.) and, pending re-examination of material assigned to both *P. rusticus* and *P. kuhlii* (now *P. hesperidus*) by Happold *et al.* (1987) and Happold & Happold (1997), no Malawi records have been mapped.

Habitat Inhabits montane and riverine forests, woodland and dry savanna, at high and low altitudes, and coastal forests and scrub. Often mist-netted over water.

Abundance Rare across distribution, but observed in comparatively large numbers at certain localities. At Messina (Limpopo Province, South Africa), *P. rusticus* comprised 22% of 60 bats (seven species) caught over three mist-net-nights in 1996 (*Nycticeinops schlieffeni*, the predominant species netted, comprised

50% of this catch). In the Waterberg region (Limpopo Province, South Africa), *P. rusticus* was the predominant species mist-netted; in 2001, it comprised 79% of 14 bats (three species) caught over three mist-net-nights; in 2004, using a larger macro mist-net, it comprised 90% of 31 bats (three species) caught over two mist-net-nights (E. Seamark & T. Kearney unpubl.).

Adaptations Aspect ratio low; wing-loading very low (Aldridge & Rautenbach 1987). Day-roosts include hollow trees (HZM). In South Africa, does not enter hibernation or prolonged periods of torpor during winter (van der Merwe & Rautenbach 1990).

Foraging and Food Forages by slow-hawking; recorded foraging between 3–18 m over a dry river bed (Smithers & Wilson 1979) and over open water (where it is most often encountered) (Rautenbach 1982). Also mist-netted in riverine forest and at dams in dry mopane veld (Rautenbach 1982), but not necessarily while foraging. Flies lower and less erratically than *P. capensis* (Shortridge 1934). Begins foraging at dusk. Insectivorous, details not known.

Echolocation Search-phase call-shape (South Africa): steep FM/QCF. Intensity high; start frequency (mean \pm S.D.) 77.8 ± 5.2 kHz; end-frequency 46.8 ± 2.4 kHz; peak-frequency 53 ± 1.8 kHz; call-duration 2.8 ± 0.6 ms (15 calls; Taylor 1999a).

Social and Reproductive Behaviour No information. A group of three was found roosting together in a tree in Zambia (HZM, Taylor 2000).

Reproduction and Population Structure Litter-size: normally two (one from each uterine horn), occasionally one; up to five conceptuses but no more than two implantations were observed (van der Merwe & Rautenbach 1990). At ca. 24° S (near Vaalwater, South Africa), the reproductive chronology is restricted seasonal monoestry, with spermatogenesis from Oct–Feb; sperm storage in ♂♂ for at least five months; copulation beginning in Apr; sperm storage in ♀♀ (Apr–Aug); ovulation and fertilization in second half of Aug; implantation in Sep; gestation estimated to be 11–12 weeks (possibly with an interval of retarded early embryonic development) and births in Nov (van der Merwe & Rautenbach 1990). Contrary to most other species of bats, in which the amnion is formed by folding, it is formed by cavitation in *P. rusticus* (van der Merwe 1994b).

Predators, Parasites and Diseases No information. Bats identified as *P. rusticus* and said to be hosts of bed-bugs *Cacodmus villosus* and *C. sparsilis* (Hemiptera: Cimicidae) by Kock *et al.* (1998b), need re-examination to confirm their identity (M. Happold pers. comm.).

Conservation IUCN Category: Least Concern.

Pipistrellus savii SAVI'S PIPISTRELLE

Fr. Vespère de Savi (Pipistrelle de Savi); Ger. Alpenfledermaus

Pipistrellus savii (Bonaparte, 1837). Fauna Ital. 1, fasc. 20. Pisa, Italy.

Taxonomy Originally *Vespertilio savii*. Traditionally *Pipistrellus savii*. Subsequently classified as *P. (Hypsugo) savii* by Hill & Harrison (1987) and Koopman (1993), *P. (Pipistrellus) savii* by Koopman (1994), and *Hypsugo savii* by Horáček & Hanák (1986), Menu (1987), Ruedi & Arlettaz (1991), Volleth & Heller (1994), Volleth *et al.* (2001), Hofer & Van Den Bussche (2003), Benda *et al.* (2004d) and Simmons (2005). Chromosomal and molecular evidence supports the generic status of *Hypsugo* but, although *savii* is the type species, it is treated here as a species of *Pipistrellus* solely for convenience (see Genus *Pipistrellus*). Synonyms: 13; none in Africa. Subspecies: four; only one in Africa. Chromosome number (Italy): 2n = 44; aFN = 50 (Capanna & Civitelli 1967).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth (but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (12–15 mm); FA: 34–38 mm; wings dark without white hind-border; pelage pale; dorsal and ventral pelage bicoloured; lower molars myotodont; inner upper incisor bicuspid; profile of forehead region of skull weakly concave to almost straight. Sexes similar. Pelage dense, soft, glossy; mid-dorsal hairs 7–8 mm. Dorsal pelage pale yellowish-brown with glossy golden sheen; hairs distinctly bicoloured with basal half to two-thirds dark brown. Ventral pelage distinctly paler; hairs yellowish-white or greyish-white with basal half blackish-brown. Naked skin of muzzle and around eyes dark brown or black. Ears dark brown or black; broader and rounder than in other North African pipistrelles. Tragus length ca. 42% of E; maximum breadth only a little less than length of anterior margin; posterior margin smoothly convex with basal lobe; tip rounded. Wing and interfemoral membranes dark brown; wings without white hind-border. Baculum as in Figure 140e (Hill & Harrison 1987).

Skull large and moderately robust for an African *Pipistrellus*. Braincase of medium relative height but relatively narrow, interorbital region relatively narrow; rostrum of medium relative length but broad (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave to almost straight. No occipital helmet. Inner upper incisor bicuspid, the posterior cusp just a little shorter than the main cusp. Outer upper incisor at least as high as the posterior cusp of the inner incisor. Anterior upper premolar absent in 10–40% of animals; if present it is minute, not visible above gum, displaced lingually;

canine and posterior premolar in contact. Lower molars myotodont. Dental formula: $2^{113}/_{3123} = 32$ or $2^{123}/_{3123} = 34$.

Geographic Variation Four subspecies recognized (Simmons 2005); only one, *P. s. ochromixtus*, in Africa.

Similar Species Two *Eptesicus* and five other *Pipistrellus* occur in North Africa (excluding *P. ariel* in S Egypt):

Pipistrellus rueppellii. Mid-ventral pelage pure white; throat sometimes pale rusty-brown.

P. deserti. Smaller (FA: 25–34 mm; GLS: 10.8–12.4 mm). Ears longer than their breadth. Wings with white hind-border. Lower molars nyctalodont.

P. kuhlii. Ears longer than their breadth. Wings with white hind-border. Inner upper incisor unicuspid. Anterior upper premolar minute, displaced lingually but usually visible. Lower molars nyctalodont.

P. pipistrellus. Smaller (FA: 28–33 mm; GLS: 11.0–11.9 mm). Ears longer than their breadth. Anterior upper premolar visible above gum. Lower molars nyctalodont.

P. hanaki. Smaller (FA: 31–33 mm; GLS: 12.1–12.7 mm). Anterior upper premolar visible above gum. Lower molars nyctalodont.

Eptesicus (2 spp.). Larger (FA: 38–52 mm; GLS: 15.3–20.1 mm). Anterior upper premolar always absent.

Distribution In Africa, mainly found in the upland and mountainous areas of the Mediterranean Coastal and Afrotropical Afroalpine BZs of NW Africa, and marginally from the adjacent Sahara Arid BZ. Recorded from Morocco (Rif, Beni Snassen, Middle Atlas, High Atlas), Algeria (Tell Atlas, Central Plateau) and Tunisia (Djebel Zaghouan) (Panouse 1955, Hill 1964, Vaughan *et al.* 1977, Aulagnier & Thévenot 1986, Kowalski & Rzebik-Kowalska 1991, Benda *et al.* 2004d). Extraliminally: southern Europe (palaeo-xeromontane element), the Canary and Cape Verde Is. and most of temperate Asia.

Habitat As in Europe (where it ranges up to 3300 m in the Sierra Nevada, Spain), inhabits rocky uplands and mountains (500–2004 m in Jbel Babor), deep valleys, cliffs and limestone areas; has also been found in a park in a town and in buildings (Gaisler 1983, Gaisler & Kowalski 1986). Several captures were recorded in sparsely vegetated

*Pipistrellus savii*

places, e.g. over water on montane grasslands surrounded by forests of Cork Oak *Quercus suber*, Green Oak *Q. ilex* or Atlas Cedar *Cedrus atlantica* (Gaisler 1983, Gaisler & Kowalski 1986). On the southern slope of the High Atlas, restricted to rare localities where palm trees *Phoenix dactylifera* grow along rivers running through rocky canyons (Fonderflick *et al.* 1988, Benda *et al.* 2004d).

Abundance Uncertain in Africa. There are few records from North Africa but this probably reflects inappropriate census methods (acoustic detection should be used). Suitable mountain habitat is widespread.

Adaptations Wing morphology not known. Flight described as quick, with wide swingings, 10–50 m above the ground (Barataud 1992). By day, roosts in holes in trees, behind bark, in rock fissures and in crevices in walls (Kowalski & Rzebik-Kowalska 1991). Migratory movements are suspected in Europe where the longest recorded movement is 250 km. In Europe, hibernates in winter; no information for Africa.

Foraging and Food Forages by fast-hawking in open spaces, sometimes above houses and treetops. Emerges shortly after sunset and forages almost all night. Feeds on small flying insects; in Switzerland, the diet was Lepidoptera, Diptera (mainly Tipulidae), Hymenoptera, Neuroptera and Hemiptera (Beck 1995).

Echolocation Search-phase call-shape (Switzerland; above canopies of trees): QCF. Start-frequency 35–38 kHz; end-frequency 30–33 kHz; call-duration 10–15 ms; inter-call interval 190 ms (Zingg 1988, Tupinier 1996).

Social and Reproductive Behaviour Very little information from Africa. In Europe, roosts singly while hibernating; maternity colonies of 20–70 ♀♀ are established in spring (Schober & Grimmberger 1987).

Reproduction and Population Structure Litter-size (SW Europe): usually two. In Europe, the reproductive chronology is restricted seasonal monoestry with mating in late Aug–Sep and births in mid-Jun to early Jul (Schober & Grimmberger 1987). No conclusive data for Africa; mating observed in Nov in Algeria.

Predators, Parasites and Diseases Ectoparasites include a flea *Ischnopsyllus octactenus* (Siphonaptera: Ischnopsyllidae) (Beaucournu & Kowalski 1985) and a tick *Argas transgaripepinus* (Acarina, Argasidae) (Médard *et al.* 1997).

Conservation IUCN Category: Least Concern (based mainly on extralimital data).

Pipistrellus somalicus SOMALI PIPISTRELLE (SOMALI SEROTINE)

Fr. Pipistrelle de Somalie; Ger. Somalia-Zwergfledermaus

Pipistrellus somalicus (Thomas, 1901). Ann. Mag. Nat. Hist., ser. 7, 8: 32. Hargeisa, Northwest Province, Somalia.

Taxonomy Originally *Vespertilio minutus somalicus*. Traditionally *Eptesicus somalicus*. Subsequently classified as *P. (Neoromicia) somalicus* by Hill & Harrison (1987) and Koopman (1994), *Nycterikaupius somalicus* by Menu (1987), *E. (Neoromicia) somalicus* by Koopman (1993) and *Neoromicia somalicus* by Simmons (2005). Synonyms: *humbloti*, *malagasyensis*, *ugandae*. Subspecies: uncertain (see Geographic Variation). The taxonomy of *P. somalicus* is problematical and its position within the *capensis*, cf. *melckorum*, *zuluensis* group is still unclear. Besides being attributed to *minutus*, it has also been considered a subspecies of *pusillus* Leconte, 1857 and of *capensis* A. Smith, 1829, but it was indicated to be a distinct species by several authors, including Matschie (1907), Rosevear (1965) and Kock (1969a). Previously, when *P. zuluensis* was thought to occur only in southern Africa, it was often considered to be a subspecies of *somalicus*, but differences in karyotype (diploid number) and the shape of the cranium support the specific status of *zuluensis*, and most of the southern African records were transferred to this species by Rautenbach *et al.* (1993). However, there are some strong indications that both *somalicus* and *zuluensis* occur in the southern part of the continent and that *zuluensis* also occurs in eastern Africa (Peterson *et al.* 1995). In West Africa, the relationship with *P. guineensis* also remains unclear. Chromosome number (Somalia): $2n = 26$; $aFN = 48$ (McBee *et al.* 1987) although there is now some uncertainty about the identity of the specimens used.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth (but only four visible above gum), five lower cheekteeth and two upper incisors on each side; ears separated and short (7–14 mm); FA: 22–32 mm; dorsal pelage brownish; dorsal and ventral hairs faintly bicoloured; wings dark, occasionally with narrow white hind-border; lower molars myotodont, inner upper incisor unicuspid or weakly bicuspid, profile of forehead region of skull weakly concave to almost straight. Sexes similar in colour; ♀♀ with forearms and metacarpals 1 mm longer on average than those of ♂♂. Pelage soft, dense, fairly fluffy; mid-dorsal hairs ca. 5–8 mm. Dorsal pelage brownish; hairs dark brown with brownish tip. Ventral pelage slightly paler; hairs brown with paler tip. In a very small number of specimens, a pale to whitish spot can be found on the throat. Ears dark brown, relatively short; outer margin convex at base, then slightly concave and then straight; tip rounded. Tragus length ca. half of E but very variable in preserved material; broadest near mid-height; anterior margin almost straight; posterior margin smoothly convex for most of its length (sometimes slightly angular just above the basal lobe); basal lobe triangular, prominent; tip rounded (Figure 136p). Wings dark brown; interfemoral membrane slightly lighter. A conspicuous white hind-border has been reported regularly in the literature but, in a sample of 102 specimens, only ca. 10% had a conspicuous hind-border, ca. 50% had a very narrow hind-border, and the remainder had no hind-border. Baculum as in Figure 141h (Hill & Harrison 1987).

Skull small and gracile for an African *Pipistrellus*. Braincase of medium relative height and breadth; interorbital region relatively narrow; rostrum of medium relative length and breadth. (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave to almost straight. No occipital helmet. Inner upper incisor usually unicuspid, occasionally weakly bicuspid; outer upper incisor very small, hardly higher than the cingulum of the inner incisor. Anterior upper premolar usually absent; if present, not visible or barely visible above gum; canine and posterior premolar in contact. Lower molars myotodont. Dental formula: usually $2^{113}/_{3123} = 32$.

Geographic Variation Uncertain. Simmons (2005) recognizes *humbloti*, *malagasyensis* and *ugandae* as subspecies. However, pending revision, no subspecies are recognized here.

Similar Species One African *Eptesicus* and seven other African *Pipistrellus* also have dark wings; bicoloured dorsal hairs; myotodont lower molars; and have (or might have) geographic ranges overlapping that of *P. somalicus* (Table 26, p. 606):

Pipistrellus capensis. Pelage conspicuously bicoloured. Ventral pelage white, whitish or cream. Dorsal hairs often shorter (5–6 mm). Forearm sometimes >32 mm. Posterior end of sagittal crest present in adults. Occipital helmet conspicuous except in young animals with unworn teeth (indicated by weakly bicuspid inner incisors). Profile of forehead region of skull almost straight.

Pipistrellus cf. *melckorum*. Larger (FA: 32–39 mm; GLS: 13.7–15.5 mm). Braincase relatively low, profile of forehead region straight to weakly concave. Tanzania to South Africa.

P. zuluensis. Dorsal pelage conspicuously bicoloured or sometimes tricoloured. Ventral pelage pale greyish-brown; hairs conspicuously bicoloured. Braincase more inflated and globular, so profile of forehead region is weakly to moderately concave.

P. ariel. Pelage conspicuously bicoloured. Ventral pelage greyish-cream. Profile of forehead region of skull distinctly concave. Outer upper incisor about two-thirds length of inner incisor. Anterior upper premolar present but minute, sometimes not visible. Sahara Arid and Sahel Savanna BZs of Sudan and perhaps Egypt.

P. inexpectatus. Dorsal hairs bicoloured; ventral pelage reddish-cream, hairs unicoloured. Inner upper incisor bicuspid; outer cusp ca. three-quarters height of main cusp. Outer upper incisor ca. half height of inner incisor. Anterior upper premolar present but not visible above gum.

P. anchietae. Pelage distinctly bicoloured. Inner upper incisor bicuspid. Anterior upper premolar present although not visible above gum. Zambezian Woodland BZ and its margins.

P. guineensis. Mid-ventral pelage dark rusty-brown, sometimes speckled; hairs bicoloured. Inner upper incisor bicuspid.

Eptesicus hottentotus. Much larger (FA: 45–54 mm; GLS: 16.9–21.5 mm).

*Pipistrellus somalicus*

Distribution Endemic to Africa. Considered to occur mainly in the Sudan and Guinea BZs from Gambia to Sudan, and in the Somali–Masai Bushland BZ in Somalia, Kenya and Tanzania. Seldom recorded in the Rainforest BZ but penetrates into all of the Rainforest–Savanna Mosaics and the Coastal Forest Mosaic BZ. Possibly extends southwards to Mozambique, Botswana, South Africa and Namibia but, because of the confusion with *Pipistrellus zuluensis* in south-central Africa and southern Africa, its occurrence south of ca. 5°S is uncertain.

Habitat Recorded as an inhabitant of ‘comparatively dry conditions’ and as having been ‘caught among trees’ (Rosevear 1965). One was mist-netted in Pandam, Nigeria, over a track through riverine forest, just where it bordered Guinea savanna (Bergmans 1977a). Aellen (1952) found one specimen in Guinea savanna in Cameroon, but considered this record surprising as it was more than 2000 km from the usual habitat of this species. Found year-round at Masalani, near Kibwezi in inland Kenya, in area of dense thorn scrub dominated by *Combretum* shrubs and stands of *Commiphora* and *Acacia* trees, with scattered patches of grassland, and riverine woodland along the Athi R. (O’Shea & Vaughan 1980). Recorded in three coastal forests in the East African Coastal Forest Mosaic (Cockle *et al.* 1998). Known altitudinal range: 380–2150 m.

Abundance Uncertain. Considered rare in West Africa (Grubb *et al.* 1998). Apparently common at some localities (e.g. Masalani, Kenya).

Adaptations Aspect ratio low (O’Shea & Vaughan 1980); wing-loading not known. Flight characteristics probably very similar to those of *P. capensis* and *P. zuluensis*. Day-roosts uncertain: an hour after sunset, Kock (1969a) observed what appeared to be one individual coming and going several times from a hole between the wall and

roof-beam of a house, suggesting that its day-roost was somewhere under the roof. Each time it came and went, it followed a fixed flight-path.

Foraging and Food At Masalani, Kenya, forages for small, flying insects by slow-hawking 2–6 m above ground (mean height 4 m) in open spaces and more than 1 m from vegetation (O’Shea & Vaughan 1980). In contrast, *P. cf. helios* (which echolocates at higher frequencies) often forages within a metre of vegetation, and these differences probably contribute to the ability of these similar species to live sympatrically (O’Shea & Vaughan 1980). Details of diet not known.

Echolocation Search-phase call-shape (Masalani, Kenya): FM sweep (no details); intensity high; start-frequency 70 kHz; end-frequency 35 kHz (n = ?; O’Shea & Vaughan 1980).

Social and Reproductive Behaviour No information.

Reproduction and Population Structure Litter-size: 2 (n = 15; O’Shea & Vaughan 1980). At 02° 19’S (Masalani, Kenya), the reproductive chronology is restricted seasonal monoestry, with parturition in the wettest month of the short wet season (Nov) (O’Shea & Vaughan 1980).

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

Pipistrellus tenuipinnis WHITE-WINGED PIPISTRELLE (SLENDER-WINGED PIPISTRELLE)

Fr. Pipistrelle à ailes blanches; Ger. Weißflügel-Zwergfledermaus

Pipistrellus tenuipinnis (Peters, 1872). Monatsber. K. Preuss. Akad. Wiss. Berlin 1872: 263. 'Guinea', no specified locality.The type locality was incorrectly restricted to Kouilou River, Congo (Ellerman *et al.* [1953], based on Noack [1889]; see Kock [1969a]).

Taxonomy Originally *Vesperus tenuipinnis*. Traditionally *Eptesicus tenuipinnis*. Subsequently classified as *Pipistrellus* (*Neoromicia*) *tenuipinnis* by Hill & Harrison (1987), Koopman (1994) and Barratt *et al.* (1995), *Nycterikaupius tenuipinnis* by Menu (1987), *E.* (*Neoromicia*) *tenuipinnis* by Koopman (1993) and *Neoromicia tenuipinnis* by Simmons (2005). Synonyms: *ater* and possibly *bicolor*. The taxonomy of *bicolor* is problematic: it was tentatively considered a synonym of *tenuipinnis* by Hayman & Hill (1971), a view followed by Simmons (2005), while Crawford-Cabral (1986) suggested the possibility that it might represent a distinct species. However, Koopman (1975) and Hill & Harrison (1987) suggested that *bicolor* might be a prior synonym of *P. anchietae* based on respective syntypes in the BMNH, which they considered essentially similar. Unfortunately, the syntypes of both *bicolor* and *anchietae* in the Lisbon Museum were destroyed by a fire in 1978 (Crawford-Cabral 1986). Furthermore, discrepancies between the original description of *bicolor* and the remaining syntype at the BMNH (Hill & Harrison 1987: 249) raise doubts about the true identity of *bicolor* (Kock 2001b). The action by Koopman (1994) to list *anchietae* as a synonym of *bicolor* was rejected by Kock (2001) as premature. Pending further evidence, *bicolor* is tentatively retained here as a synonym of *P. tenuipinnis*, and *P. anchietae* is tentatively retained as a valid species. Subspecies: uncertain (see Geographic Variation). Chromosome number (Cameroon): $2n = 36$; $aFN = 52$ (McBee *et al.* 1987). Karyotypic data support the inclusion of *tenuipinnis* within *Neoromicia* (McBee *et al.* 1987).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth; ears separated and short (10–14 mm); FA: 28–33 mm; wings pale, contrasting strongly with dark dorsal pelage (cf. *P. rendalli*); dorsal hairs usually unicoloured, ventral hairs bicoloured; lower molars myotodont; inner upper incisor weakly bicuspid; profile of forehead region of skull weakly concave. Sexes similar. Pelage silky, dense; mid-dorsal hairs ca. 6 mm. Dorsal pelage blackish-brown; hairs usually unicoloured, sometimes slightly paler at tip. Ventral pelage whitish or cream, throat and upper chest darker; hairs blackish-brown at base with silvery-white or cream at tip. Ears pale grey to pale brown, subtriangular; anterior margin straight, posterior margin slightly concave, tip rounded; 35–47% of FA. Tragus length 32–50% of E; relatively broad, widest above mid-point; anterior margin almost straight; posterior margin with sharp angle ca. one-quarter distance from tip, giving tragus a truncated appearance; tip rounded (Figure 136c). Wing-membranes white to pale yellow when folded, transparent when stretched out. Interfemoral membrane usually pigmented, thus darker than wing-membranes. Tibia, hind-foot and forearm reddish-brown, the latter in strong contrast to the unpigmented wing-membranes. Penis fairly long (5.5 mm). Baculum as in Figure 141i (Hill & Harrison 1987); tip expanded into an almost vertical, lobed, plate-like structure.

Skull medium-small and gracile for an African *Pipistrellus*. Braincase relatively high but of medium relative breadth; interorbital region of medium relative breadth; rostrum relatively short but broad (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly concave; skull sloping almost uniformly from muzzle to occiput. No occipital helmet. Inner upper incisor broad to very broad, weakly bicuspid. Outer upper incisor unicuspid, variable in length (one-third to two-thirds height of inner incisor). Anterior upper premolar either absent or present (sometimes only on one side), if present, almost always visible above gum and displaced lingually into recess between canine and posterior premolar; canine and posterior premolar in contact. Lower molars myotodont. Dental formula: $2^{113}/_{3123} = 32$ or $2^{123}/_{3123} = 34$.

Geographic Variation Little variation in size but, even within populations, there is some variability in colour. Koopman (1994) recognized two subspecies, *P. t. tenuipinnis* (Senegal to DR Congo) and *P. t. ater* (NE DR Congo and Kenya to Angola). However, the distribution of *P. tenuipinnis* is contiguous throughout DR Congo to Uganda and specimens from Angola, allocated by Koopman to *P. t. ater*, do not appear to be geographically separated from those in SW DR Congo, which belong to the nominate form according to Koopman. Pending a revision of this species, which should include the critical examination of *bicolor* (see Taxonomy), no subspecies are recognized here.

Similar Species Three other African vespertilionids have white wings:

Pipistrellus rendalli. Dorsal pelage pale to medium-pale brown, not in strong contrast with the pale wings. On average larger (FA: 32.7 [29–36] mm). Inner upper incisor unicuspid with small basal cusp (the latter not always visible). Mostly in drier habitats.

Scotoecus albobfuscus. Only one upper incisor on each side. Penis extremely long.

Glauconycteris gleni. Dark brown pigment over wing bones; brown reticulation lines on arm-wing. Outer margin of ear reaching mouth; lower lip with lobe at posterior corner.

Distribution Endemic to Africa. Recorded from the Rainforest BZ (Western, West Central, East Central and South Central Regions) and the adjacent Rainforest–Savanna Mosaics, Afromontane–Afroalpine BZ and marginally from the Guinea Savanna BZ. Recorded disjunctly from Guinea and Sierra Leone to SW Kenya and southwards to N Angola, S DR Congo and N Tanzania, with rather isolated records from Senegal, Guinea-Bissau and SW Ethiopia. Apparently absent from most of the Dahomey Gap in West Africa (only known from Bismarckburg in Togo and not yet recorded from Benin). Also, not yet recorded from mainland Equatorial Guinea. Most of the localities in Kenya, Tanzania and Ethiopia have been

*Pipistrellus tenuipinnis*

recorded from riverine forests, montane forests, or near lakes along the Rift Valley.

Habitat Mostly recorded in lowland rainforest, swamp forest and coastal forest; also recorded from montane forest, mangroves, forest–savanna mosaic, *Isberlinia* woodland, *Acacia–Commiphora* bushland and thicket and miombo woodland. Within the Rainforest BZ, seems to prefer drier types of forest along the periphery of the rainforest. In West Africa, apparently restricted to lower altitudes, but reported at 3000 m in Rwanda (Rwankwi; Hayman *et al.* 1966). Also recorded from degraded forests as well as orchards and plantations; on Bioko I., primarily caught in cocoa plantations (Schlitter *et al.* 1982, Juste & Ibáñez 1994, USNM). In drier areas, it is associated with riverine and relict forests, and is commonly caught in nets set over rivers and pools (Duckworth *et al.* 1993, ROM, USNM).

Abundance No detailed information but comparatively abundant.

Adaptations Day-roosts very varied: this species has been found roosting in hollow standing trees, under boulders, in roofs and under eaves of huts and houses, and also in thatch and in crevices in walls and around windows (Lang & Chapin 1917b, Novick 1958b, Aellen 1963, Rosevear 1965, Roche 1972, Grubb *et al.* 1998, MHNG, USNM).

Foraging and Food Forages by slow- to moderately fast-hawking in spaces with background clutter and in open spaces. In Comoé N. P., Côte d'Ivoire, five individuals were caught at a median height of 12 (4–23) m in mist-nets set from 0 to 25 m above ground. Frequently attracted to light, and often enters rooms (Eisentraut 1956, Rosevear 1965). Diet not known; based on body-size, likely to consume very small flying insects.

Echolocation Call-shape (DR Congo) steep FM/QCF. Novick (1958b) reported start-frequency 62 (39–83) kHz; end-frequency 37 (24–42) kHz; and call-duration 1.5 (0.9–1.9) ms. However, this needs confirmation using modern equipment.

Social and Reproductive Behaviour Roosts singly and in groups. One group (in a hollow tree), was comprised of two ♂♂, four ♀♀ and one unsexed (Allen 1917a, Lang & Chapin 1917b). Sometimes found 'in considerable numbers' in crevices in the structure of houses (Rosevear 1965). Has been found singly and in groups of up to six (T. S. Jones in Grubb *et al.* 1998).

Reproduction and Population Structure Litter-size: one ($n = 3$). Reproductive chronology not known. In Uganda, there are records of a pregnant ♀ in early Dec (01° 12' N, Bugoma Forest), three lactating ♀♀ in Jan (locality not specified), and a pregnant ♀ in late Feb (00° 5' S, Sango Bay Forest); no data for other months or for other ♀♀ captured in these months (Kingdon 1974, LACM). Males with very large testes were noted in Jun, Oct and Nov; the facial glands of these ♂♂ were very large and exuded a greasy orange secretion that tinted the entire animal, including its wings, with a pinkish colour, and the hair on the face seemed to be less dense at this time (Kingdon 1974). One ♀ from Sierra Leone (near Fintonia, 09° 40' N) was lactating in mid-May (USNM), and in Cameroon (Isongo, 04° 05' N) one ♀ was pregnant in early Mar (Eisentraut 1956). These data are inconclusive.

Predators, Parasites and Diseases Predators include Bat Hawks *Macheiramphus alcinus* (Lang & Chapin 1917b) and a tree snake *Toxicodryas blandingii* (Jones 1961). Ectoparasites include a bed-bug *Aphrania elongata* (Hemiptera: Cimicidae); bat-flies *Raymondia intermedia* (Diptera: Streblidae), *Basilia ansifera*, *B. robusta* (Diptera: Nycteribiidae); a tick *Carios boueti* (Acari: Argasidae); and mites *Spinturnix aelleni* (Acari: Spinturnicidae), *Steatonyssus afer*, *S. javensis* (Acari: Macronyssidae), *Pteracarus holubi* (Acari: Myobiidae), *Alabidocarpus eptesicus* (Acari: Chirodiscidae) and *Notoedres schoutedeni* (Acari: Sarcoptidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

This species is apparently able to exploit altered and degraded habitats and seems to be less adversely affected by deforestation than other forest bats.

Measurements

Pipistrellus tenuipinnis

FA: 29.8 (28–33) mm, $n = 31$

WS (d): 212 (200–228) mm, $n = 13$

Pipistrellus zuluensis ZULU PIPISTRELLE (ALOE BAT)

Fr. Pipistrelle zouloue; Ger. Zulu-Zwergfledermaus

Pipistrellus zuluensis (Roberts, 1924). Ann. Transvaal Mus. 10: 60. White Umfolosi G. R., KwaZulu–Natal, South Africa.

Taxonomy Originally and traditionally *Eptesicus zuluensis*. Subsequently classified as *P. (Neoromicia) zuluensis* by Hill & Harrison (1987), *Nycterikaupius zuluensis* by Menu (1987), *E. (Neoromicia) zuluensis* (as a synonym of *E. (Neoromicia) somalicus*) by Koopman (1993), *P. (Neoromicia) somalicus zuluensis* by Koopman (1994) and *Neoromicia zuluensis* by Kearney *et al.* (2002) and Simmons (2005). Considered closely related to *P. somalicus*, and much of the literature on *zuluensis* is mentioned under *somalicus*. Synonyms: *vansoni*. Subspecies: uncertain (see Geographic Variation). Chromosome number (South Africa): 2n = 28; aFN = 48 (Morales *et al.* 1991, Rautenbach *et al.* 1993, Kearney *et al.* 2002). Based on chromosomal differences, Rautenbach *et al.* (1993) regard *zuluensis* as specifically distinct from *somalicus*.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth (only four usually visible), five lower cheekteeth and two upper incisors on each side; dorsal pelage medium brown; dorsal hairs bicoloured or tricoloured, ventral hairs bicoloured; wings dark, usually without white hind-border; lower molars myotodont; inner upper incisor usually unicuspid; profile of forehead region of skull weakly to moderately concave. Sexes similar. Pelage soft, dense, without sheen; mid-dorsal hairs 6–7 mm (9–10 mm on rump). Dorsal pelage medium brown, sometimes paler on rump; some individuals have a slightly orange hue (but none reddish as in *P. rusticus*); hairs blackish-brown (sometimes with paler middle section) and medium to pale brown at tip. Ventral pelage paler and more greyish; hairs very dark grey with pale greyish-brown or grey at tip. Ventral pelage not noticeably paler in pelvic region although some all-white hairs are present. Forehead sometimes raised (cf. straight in *P. capensis*). Ears brown, relatively short, subtriangular; tip rounded. Tragus length ca. half of E but very variable in preserved material; anterior margin smoothly concave; posterior margin smoothly convex for most of length (but with shallow rounded angle just below mid-height) and with a prominent, folded, triangular basal lobe; tip rounded. Eyes very small. Wings dark brown, slightly translucent, usually without white hind-border but sometimes with very narrow hind-border. Interfemoral membrane dark brown, slightly translucent; tail fully enclosed except for part of last vertebra. Baculum as in Figure 141j, k, (Hill & Harrison 1987, Kearney *et al.* 2002).

Skull small and gracile for an African *Pipistrellus*. Braincase relatively high and narrow; interorbital region relatively narrow; rostrum relatively short and narrow (Table 25, p. 603). Profile of forehead region (viewed laterally) weakly to moderately concave. Occipital helmet absent, therefore braincase smoothly rounded

posteriorly (cf. *P. capensis*). With experience, the globular braincase, concave forehead and lack of helmet can be felt without removing the skull. Inner upper incisor large, usually unicuspid but sometimes bicuspid. Outer upper incisor small, ca. half height of inner incisor, higher than cingulum of inner incisor but lower than the secondary cusp, if present. Anterior upper premolar almost always absent: if present, it is extremely minute and hardly visible above gum. Lower molars myotodont. Dental formula: usually $2^{113}/_{3123} = 32$.

Geographic Variation Possibly *vansoni* Roberts, 1932, from NE Botswana, N Namibia and perhaps Angola, might represent a valid subspecies.

Similar Species One African *Eptesicus* and five other African *Pipistrellus* also have dark wings, bicoloured dorsal hairs and myotodont lower molars, and have (or might have) geographic ranges overlapping that of *P. zuluensis* (see also Table 26, p. 606):

Pipistrellus capensis. Dorsal hairs bicoloured. Ventral pelage white, whitish or cream. Braincase relatively low; rostrum relatively longer and broader; profile of forehead region straight to weakly concave. Occipital helmet usually present, therefore braincase not smoothly rounded posteriorly. Outer upper incisor usually less than half the height, but above the cingulum, of the first incisor.

P. cf. melckorum. Skull longer (GLS: 13.7–15.5 mm). Forearm usually longer (32–39 mm). Braincase relatively low, profile of forehead straight to weakly concave; occipital helmet present although weakly developed. Inner upper incisor always unicuspid.

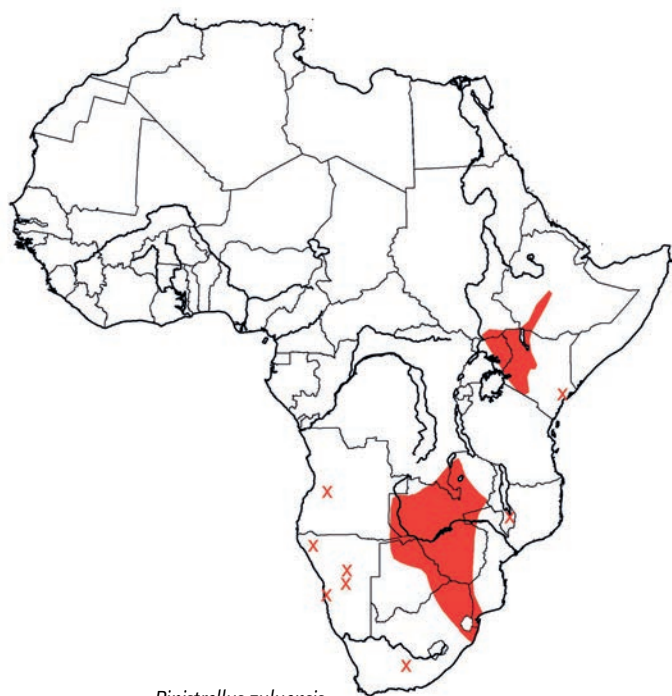

P. somalicus. Pelage only slightly bicoloured. Ventral pelage brown. Forehead only slightly raised – head feels flat. Braincase less inflated and less globular so profile of forehead region is only weakly concave. Outer upper incisor less than half the height, but above the cingulum, of the inner incisor.

P. anchietae. Dorsal hairs bicoloured (never tricoloured). Inner upper incisor bicuspid. Anterior upper premolar present but minute, not visible.

P. guineensis. Dorsal hairs bicoloured (never tricoloured). Ventral pelage dark rusty-brown, sometimes speckled. Inner upper incisor bicuspid. Geographic range might overlap in Uganda, S Sudan and Ethiopia.

Eptesicus hottentotus. Much larger (FA: 45–54 mm; GLS: 16.9–21.5 mm).

Distribution Endemic to Africa. Recorded mainly from the Somalia–Masai Bushland, Zambezian Woodland and South-West

*Pipistrellus zuluensis*

Arid BZs, with some records in some of the adjacent biotic zones. Recorded from scattered and sometimes apparently isolated localities in south-central Africa and southern Africa from Angola to Malawi and southwards through Namibia, Zambia, Zimbabwe, Botswana and South Africa, and recently found to occur also in Kenya (based on examination of material at ROM), Ethiopia (ZFMK) and Sudan (FMNH, SMF) (V. Van Cakenberghe unpubl.). Koopman (1975), who considered it highly probable that *zuluensis* was conspecific with *somalicus*, drew attention to an apparent gap in the distribution of these two forms, but the new data indicate that this gap is non-existent and that the distributions of *zuluensis* and *somalicus* overlap. Not yet recorded from Swaziland, but likely to occur there.

Habitat Records from Kenya, Ethiopia and Sudan are in semi-desert grassland and shrubland, and in *Acacia-Commiphora* deciduous bushland and thicket vegetation zones (terminology: White 1983). In south-central Africa and southern Africa, exploits woodland savanna habitats (including miombo woodland), and drier shrublands and bushlands in the South-West Arid Zone. Known altitudinal range: 500–2650 m.

Abundance Uncertain. Seldom recorded in Malawi (Happold & Happold 1997). Not as common as *P. capensis* in southern Africa (Taylor 2000).

Adaptations Aspect ratio low; wing-loading very low. Flight speed moderate; manoeuvrability high; can take off from ground. Turns by banking (minimum radius of turn <25 cm), and by stalling-and-twisting. Individuals could fly across a 1×1×1 m enclosure, but were not able to complete more than two circuits/flight (2 bats, 10 flights each). Scuttling over horizontal, sloping and vertical surfaces is fairly efficient although not fast. Day-roosts not known. Although Roberts (1924) used the name Aloe Bat in his description, it was

not *P. zuluensis* but *P. capensis* that he found roosting among the leaves of aloes (Smithers 1983). In Malawi, at 20–21 °C, becomes torpid during the day. A captive individual, fed winged termites and able to fly, drank water irregularly, the longest interval between drinks being 3.5 days in a 9-day trial. In the Namib Desert, captive bats exposed to prevailing desert conditions, but unable to fly, were able to rear young when deprived of water (Roer 1970, 1971). Predicted mean maximum urine concentration comparatively very high – 5010 mOsmol/kg in bats from the Namib Desert (Geluso 1980) and 4709 mOsmol/kg in bats from Malawi (Happold & Happold 1988). The predicted urine concentrating capacity of the bats from the Namib Desert is the highest known for bats. However, because of the high rate of evaporative water loss from the wings during flight, the species is unlikely to be independent of drinking water in the wild.

Because *P. zuluensis* and *P. somalicus* have often been confused and/or regarded as conspecifics, it is likely that further information about *P. zuluensis* has been recorded as pertaining to *P. somalicus*.

Foraging and Food In miombo woodland in Liwonde N. P., Malawi, forages by slow-hawking in spaces with moderate to high levels of clutter, including near canopies of trees, glades in woodland, open spaces between tree-trunks and lower branches, and clearings around buildings. Unlike many other species in this habitat, not recorded over a pool in the Likwenu R. on any of four occasions (M. Happold unpubl.), although one was caught over this river by David Harrison (pers. comm.). In contrast, T. Kearney (pers. obs.) caught some over a small man-made pond in dry mopane woodland and over a larger dam in the Waterberg, South Africa, but it is not known if they were foraging or coming to drink. Morphometric data suggest that this species does forage over water as well as in other places (Fenton & Bogdanowicz 2002). Diet includes moths and beetles (Fenton *et al.* 1998a, Taylor 2000).

Echolocation Search-phase call-shape (cluttered environment, Malawi) steep FM/QCF with the QCF ‘heels’ short (Figure 118c) to long. Intensity high; start-frequency up to 79 kHz; end-frequency and peak-frequency 48–50 kHz; maximum duration 5.5 ms (two bats, tethered, 175 calls; M. Happold unpubl.).

Social and Reproductive Behaviour No information.

Reproduction and Population Structure At 15°S (Liwonde N. P., Malawi), of a total of four adult ♀♀, one was pregnant with two embryos in Oct, one was lactating in Nov, one was post-lactating and another was reproductively inactive in Feb. A juvenile was recorded in Dec and two subadults in Apr. Two ♂♂ with abdominal testes were recorded in Nov, Dec; one with scrotal testes in Jun. Although inconclusive, these data are consistent with restricted seasonal monoestry with births early in wet season (Happold & Happold 1990a). At 22°23'S in South Africa, a lactating ♀ was recorded in Nov (T. Kearney pers. obs.).

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

GENUS *Plecotus*

Long-eared Bats

Plecotus E. Geoffroy, 1818. Description de l'Égypte 2: 112. Type species: *Vesperilio auritus* Linnaeus, 1758.

Plecotus christii.

This Old World genus currently contains at least 19 species of which three occur in Africa (Benda *et al.* 2004c), Spitzenberger *et al.* 2006). Diagnostic combination of characters: five upper and six lower cheekteeth and two upper incisors on each side; ears comparatively and relatively long (32–40 mm in African species; almost as long as forearm) and joined at base across the forehead (Figure 142). The tragus is long, reaching half the length of the ears; it remains erect when the ears are folded while the bats rest. The muzzle is coniform; the nostrils open upward with the orifices extending backward by a slit-like prolongation. The eyes are large for a microbat. The tail is long (ca. same as HB), and the terminal vertebra extends ca. 1.0–1.5 mm beyond the margin of the interfemoral membrane. The wings are short and broad. The distal part of the glans penis is broad (broadest part ca. 2.5–3.0 mm) and rounded. The bacula vary inter-specifically in shape (Figure 143). The skull has a large, elongate and rounded braincase, but the rostrum is slender and reduced (Figure 142). The supraorbital ridges are well developed and the tympanic bullae large. For African species, the profile of the forehead region (viewed laterally) varies from comparatively strongly concave (Figure 142c) to comparatively weakly concave (Figure 142d), but the variation is slight compared with that in other genera (e.g. *Glauconycteris*, *Pipistrellus*, *Myotis*). Dental formula: $2^{123}/_{3133} = 36$. The upper incisors are well developed, each with a distinct secondary cusp, the inner incisor is much smaller than the outer. The anterior upper premolar is very small, and is either situated in the tooththrow or displaced lingually. The upper molars are short on their lingual sides, and the spaces between their crowns are unusually large. Of the three lower premolars, the middle is the smallest.

Morphologic, bacular and karyotypic data suggest close affinity with *Barbastella*, *Otonycteris* and three other non-African genera (e.g.

LEFT: Figure 142. *Plecotus*. (a) Flight membranes, and bones of wing, hindlimb and tail of a non-African species (*P. austriacus*). (b) Head of *P. gaisleri* showing details of the left ear and tragus (based on photos in Benda *et al.* 2004c). (c) Lateral view of skull of *P. gaisleri* and (d) lateral view of skull of *P. christii* (both based on Benda *et al.* 2004c). For African *Plecotus*, the forehead region is comparatively strongly concave in *P. gaisleri* and weakly concave in *P. christii*.

ABOVE: Figure 143. Bacula of *Plecotus* occurring in Africa. (a) *P. balensis*, holotype (based on Kruskop & Lavrenchenko 2000). (b) *P. christii* (based on Lanza 1960 in Benda *et al.* 2004c). (c) *P. gaisleri* (based on Qumsiyeh 1985 as *P. austriacus austriacus*, in Benda *et al.* 2004c). For further examples, see Benda *et al.* 2004c). All are dorsal views with tip uppermost. Scale = 1 mm.

Hill & Harrison 1987, Frost & Timm 1992, Tumilson & Douglas 1992, Qumsiyeh & Bickham 1993); mitochondrial ribosomal sequences support the relationship with *Barbastella*, but not *Otonycteris* (Hoofer & Van Den Bussche 2001). Simmons (2005) places *Plecotus* in the tribe Plecotini, with both *Barbastella* and *Otonycteris* and three non-African genera. All *Plecotus* in Africa were formerly thought to represent *P. auritus* and then *P. austriacus*. Subsequently, *P. balensis* from Ethiopia was described as distinct from *P. austriacus* by Kruskop & Lavrenchenko (2000), *P. austriacus christii* from NE Africa and N Sudan was restored to specific status by Benda *et al.* (2004c), and these authors also found that specimens from Cyrenaica in NE Libya and the Maghreb in NW Africa represent two subspecies of *P. teneriffae*. Then Spitzenberger *et al.* (2006) revised the whole genus and concluded it contains at least 19 species, which are more or less cryptic. They also recognized three species in Africa but concluded that the populations in Cyrenaica and the Maghreb represent two subspecies of *P. kolombatovici* (*P. k. gaisleri* and an as yet unnamed subspecies, respectively). Subsequently, *gaisleri* was raised to specific status by Mayer *et al.* (2007) and the undescribed subspecies apparently belongs to this species. The *Plecotus* species profiles were updated in 2011 to embrace these changes in taxonomy.

Collectively, the African species inhabit a great variety of forests, semi-covered and open habitats; two species extend into desert regions but are found only near oases. Little is known about the habits of the African species but, as a general rule, *Plecotus* emerge from their roosts only after dark for intermittent periods of activity throughout the night. They appear to fly quite fast when they commute along hedges between roosts and feeding areas. When they forage, their flight is slow and fluttering, and they can hover briefly. Their prey is often gleaned from the foliage of trees or bushes, and from the walls of buildings. They feed mainly on Lepidoptera without using any echolocation. When the bats are travelling, they emit very

low FM calls that are only detectable over short distances. *Plecotus* are gregarious in summer, the usual number of individuals averaging 10–20 per colony. In winter they are more solitary, particularly the individuals that hibernate in deep cracks.

Fossil evidence of *Plecotus* has been recorded from the Miocene of Europe where it diversified during the Pliocene and Pleistocene (Sigé & Legendre 1983). No palaeontological record is available in Africa.

The three species in Africa are distinguished by their distributions and the following characters:

P. balensis. Dorsal pelage dark rusty-brown, hairs tricoloured with basal two-thirds dark. Ears dark brown or blackish-brown. Wings brown, heavily pigmented. Braincase breadth 50–53% of GLS. Profile of forehead region of skull (viewed laterally) comparatively weakly concave. Ethiopia.

P. christii. Dorsal pelage very pale brown or greyish-brown; hairs tricoloured with basal half dark. Ears unpigmented except around tip. Wings pale, semi-translucent. Braincase breadth 45–51% of GLS. Profile of forehead region comparatively weakly concave (Figure 142d). NE Sahara (Libya, Egypt, N Sudan).

P. gaisleri. Dorsal pelage greyish-brown; hairs tricoloured with basal half dark. Ears dark brown to dark greyish-brown. Wings dark brown to dark greyish-brown. Braincase breadth 47–51% of GLS. Profile of forehead region comparatively strongly concave for an African *Plecotus* (Figure 142c). The Maghreb and Cyrenaica.

Note that the concavity of the forehead region in all of these species is weak, and shows very little variability, in comparison with that in genera such as *Glauconycteris*, *Pipistrellus* and *Myotis*.

Stéphane Aulagnier

Plecotus balensis BALE LONG-EARED BAT

Fr. Oreillard d'Ethiopie; Ger. Bale-Langohr

Plecotus balensis Kruskop & Lavrenchenko, 2000. Myotis 38: 6. Hareenna Forest, Bale Mts, Ethiopia, ca. 06° 45' N, 39° 44' E, alt. 2760 m.

Taxonomy Synonyms: none. Multivariate analysis of morphological characters shows that *Plecotus* from Ethiopia (the southernmost part of the genus range) is clearly differentiated from *P. austriacus*, which was previously considered the only species of *Plecotus* in Africa. Species status confirmed by bacular morphology. Chromosome number (Ethiopia): 2n = 32 (Kruskop & Lavrenchenko 2000); aFN not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and six lower cheekteeth and two upper incisors on each side; ears joined at base, large for a vespertilionid (E: 37–40 mm) and relatively enormous (ca. 97% of FA); dorsal pelage dark rusty-brown, hairs with basal two-thirds dark; face, ears and wings dark; muzzle conspicuously inflated behind nostrils. Sexes apparently similar. Pelage moderately long, dense. Dorsal pelage dark rusty-brown; hairs tricoloured with basal two-thirds dark brown (cf. *P. christii*, *P. gaisleri*), terminal third grey with greyish-brown at tip. Ventral pelage whitish

or pale grey; hairs dark grey with whitish or pale grey tip. Muzzle narrow, conspicuously inflated behind nostrils; supraorbital gland comparatively small (ca. 1 mm in diameter). Naked parts of face brown. Ears dark brown or blackish-brown, relatively long (ca. 97% of FA and therefore look enormous); inner margins joined by low band across forehead. Tragus moderately long (ca. just under half of E), tapering to blunt point. Eyes relatively large for a microbat. Wing-membranes brown, heavily pigmented; skin over wing-bones and hindlimbs blackish-brown. Thumb comparatively short (5.74 [5.4–6.2] mm). Interfemoral membrane brown; calcar reaching ca. half-way to tip of tail. Baculum Y-shaped; lateral arms long, narrow, with obtuse angle between them (Figure 143a; Kruskop & Lavrenchenko 2000).

Skull medium-sized for a *Plecotus*, with braincase of medium relative height but very broad (braincase breadth 50–53% of GLS) (Benda *et al.* 2004c). Profile of forehead region (viewed laterally) weakly concave for an African *Plecotus* (cf. *P. gaisleri*). Rostrum relatively short (C–M³: 32–33% of GLS) and relatively narrow (width between canines 65–68% of C–M³). Tympanic bullae comparatively small (largest

vertical diameter 4.42 [4.28–4.53] mm, $n = 6$). Dentition weaker than in *P. gaisleri*. Anterior upper premolar medium-sized (length 0.46–0.49 mm; breadth 0.41–0.50 mm); displaced lingually but canine and posterior premolar well separated. For more information, see Kruskop & Lavrenchenko (2000) and Benda *et al.* (2004c).

Geographic Variation None.

Similar Species The only other vespertilionids in Africa that have ears with inner margins joined are:

Plecotus christii. Dorsal hairs with basal half dark rusty-brown; tip colour more prominent so pelage appears paler. Ears unpigmented except around tip. Wings pale, semi-translucent. Braincase and rostrum usually relatively narrower (details in Description). Baculum Y-shaped with acute angle between lateral arms. NE Sahara (Libya, Egypt, N Sudan).

P. gaisleri. Dorsal hairs with basal half dark rusty-brown. Skull with frontal region deeply concave. Rostrum usually relatively longer and broader (details in Description). Baculum Y-shaped with acute angle between lateral arms. Morocco to Libya.

Barbastella (2 spp.). Ears much shorter (13–18 mm). Only five lower cheekteeth and one upper incisor on each side.

Only one other vespertilionid in Africa has long ears (>28 mm):

Otonycteris hemprichii. Ears with inner margins not joined at base. Only four upper and five lower cheekteeth and one upper incisor on each side.

Distribution Endemic to Africa. Only known from the Afromontane–Afroalpine BZ of the Ethiopian Highlands on both sides of the Rift Valley. Recorded from the upper belt of the Harennā Forest on the Bale Mts, Ethiopia, from 2500–3000 m (Yalden 1988a, Kruskop & Lavrenchenko 2000), and from Abune Yosef (Benda *et al.* 2004c). There is also an early record from ‘Shoa’ (= Shewa), which probably came from the uplands N or NW of Addis Ababa (Kruskop & Lavrenchenko 2000).

Habitat In the Bale Mts, found in humid afromontane *Schefflera*–*Hagenia* and *Erica arborea* forest.

Abundance A relatively common bat in its habitat (according to sighting records).

Remarks Forages by slow-hawking and perch-hunting in open parts of the forest and near edges of clearings. Calls (? social) have been heard, but echolocation calls were not detectable with a QMC-mini narrow-band detector, suggesting that they are of very low intensity, as in *Plecotus auritus* (western Europe to Japan), which also forages in cluttered forest environments. It has been suggested that the ancestor of *P. balensis* came from comparatively arid habitats (now inhabited by *P. austriacus*), and that adaptation to the Ethiopian montane forest

Plecotus balensis

resulted in convergence with *P. auritus* (Kruskop & Lavrenchenko 2000, Lavrenchenko 2000). The convergent characters include darker colouration, the noticeably inflated muzzle behind the nostrils, smaller bullae and weaker dentition.

Conservation IUCN Category: Vulnerable.

Very small area of occupancy. Protected by Bale Mountains N. P.

Plecotus christii CHRISTIE'S LONG-EARED BAT

Fr. Oreillard d'Egypte; Ger. Christies Langohr

Plecotus christii Gray, 1838. Mag. Zool. Bot. 2: 495. Nile Valley between Qena and Aswan, S Egypt (restricted by Qumsiyeh 1985).

Taxonomy Formerly identified as *P. auritus*, and more recently considered a subspecies of *P. austriacus* (e.g. Simmons 2005). However, a systematic revision of African populations of *Plecotus* indicates that it is a distinct species morphologically and genetically close to *P. balensis* (Benda *et al.* 2004c). Synonyms: *aegyptius*, *aegyptiacus*. Subspecies: none. Because it was named after Dr Turnbull Christie, the species name is often spelt *christiei*, but the original spelling is *christii*. Chromosome number (Jordan): $2n = 32$, $aFN = 50$ (Qumsiyeh & Bickham 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and six lower cheekteeth and two upper incisors on each side; ears joined at base, large for a vespertilionid (E: 32–39 mm) and relatively enormous (ca. 97% of FA); dorsal pelage very pale brown or greyish-brown, hairs with basal half dark; face and ears pale; wings pale and semi-translucent; muzzle moderately inflated behind nostrils. Sexes similar. Pelage dense, soft, slightly woolly; mid-dorsal hairs ca. 7 mm. Dorsal pelage very pale umber brown or greyish-brown; hairs tricoloured with basal half rusty-brown, terminal half pale brownish-grey with umber brown or pale brown at tip (middle colour palest). Ventral pelage whitish; hairs dark rusty-brown with creamy or white tip. Face pinkish-grey to pale greyish-brown. Muzzle blunt, inflated behind nostrils; supraorbital gland comparatively small, ca. 0.9 mm diameter (cf. *P. gaisleri*); naked parts of face pale greyish-brown. Ears translucent, unpigmented except for pale brown tips; relatively long (97 [89–100]% of FA and therefore look enormous); inner margins joined by low band at base. Tragus mostly translucent but brownish around distal margins, moderately long (48 [46–50]% of E), 5 mm at widest, tapering to blunt point. Eyes relatively large for a microbat. Wings with arm-wing membrane creamy, hand-wing membrane translucent, pale grey; skin over wing-bones pale brown. Thumb comparatively short, on average 5.5 mm long (cf. *P. gaisleri*). Interfemoral membrane cream. Baculum Y-shaped; lateral arms short, broad, with acute angle between them (Figure 143b).

Skull small for a *Plecotus*, with braincase of medium relative height but long and narrow (braincase width 45–51% of GLS) (Benda *et al.* 2004c). Profile of forehead region (viewed laterally) comparatively weakly concave for an African *Plecotus* (Figure 142d) (cf. *P. gaisleri*). Rostrum relatively short ($C-M^3$: 32–33% of GLS), low and relatively very narrow (width between canines 62–65% of $C-M^3$). Tympanic bullae medium-sized (largest vertical diameter 4.47 [4.3–4.6] mm, $n = 6$). Dentition more gracile than in *P. balensis* and *P. gaisleri*. Anterior upper premolar comparatively small (length 0.37–0.44 mm, breadth 0.41–0.50 mm); within tooththrow; canine and posterior premolar well separated.

Geographic Variation No subspecies described, however individuals from Sinai and Palestine are larger on average than those from the Nile Valley and Siwa Basin (Qumsiyeh 1985, P. Benda unpubl.). Further research necessary, but the differences in size suggest subspecific status for the north-eastern populations.

Similar Species The only other vespertilionids in Africa which have ears with inner margins joined are:

Plecotus balensis. Dorsal hairs with basal two-thirds dark brown; tip colour less prominent so pelage appears darker. Ears dark brown or blackish-brown. Wings dark, heavily pigmented. Braincase and rostrum usually relatively broader (details in Description). Baculum Y-shaped with obtuse angle between lateral arms. Ethiopia, possibly Eritrea.

Plecotus gaisleri. Ears dark brown to greyish-brown. Wings dark, heavily pigmented. Muzzle not inflated behind nostrils. Skull with frontal region more strongly concave; rostrum relatively broader and usually relatively longer (details in Description). Baculum Y-shaped, robust, with comparatively long lateral arms. Morocco to Libya.

Barbastella (2 spp.). Ears much shorter (14–18 mm). Only five lower cheekteeth and one upper incisor on each side.

Only one other vespertilionid in Africa has long ears (>28 mm):

Otonycteris hemprichii. Ears with inner margins not joined at base. Only four upper and five lower cheekteeth and one upper incisor on each side.

Distribution In Africa, only known from the Sahara Arid BZ. Confirmed records are from the oases of Siwa and Al Jaghbub near the Libyan–Egyptian border, from the Nile Valley (from the Delta in Egypt to the Fifth Cataract in N Sudan), and from oases in Sinai

*Plecotus christii*

(Kock 1969a, Gaisler *et al.* 1972, Qumsiyeh 1985, P. Benda *et al.* unpubl.). Old records from Eritrea and Ethiopia are now assigned to *P. balensis*. Extraliminally: SW Jordan and S Palestine. Harrison & Bates (1991) provisionally identified specimens from the Arabian Peninsula as *P. austriacus christii*, but this bat lives only in the deserts along the Rift Valley (Jordan, Palestine); in N Arabia, only *Plecotus macrobullaris* has been confirmed (Benda *et al.* 2004c), and the population provisionally assigned to *P. christii* from Yemen and SW Saudi Arabia needs revision.

Habitat All records are from open areas of oases in very dry deserts, and from mesic habitats along the Nile R., where suitable day-roosts are available.

Abundance Probably rare. However, in Sinai, it was one of the bats that was recorded comparatively frequently.

Remarks Wings broad; this species is well adapted for hovering and forages by gleaning, often picking insects off leaves and blossoms. In Israel, feeds predominantly on medium-sized and large Lepidoptera (Noctuidae and Hepialidae) and occasionally on Coleoptera (Scarabaeidae), Diptera and Trichoptera (Whitaker *et al.* 1994, Feldman *et al.* 2000). By day, roosts mainly in rocky cavities, but also roosts in dark areas of pyramids, old monuments, ruins, caverns and abandoned mines where individuals hang from the walls. Sedentary; the home-range is restricted to the oasis. Usually found to be solitary. Males become territorial in autumn, when mating occurs. Litter-size: one ($n = 1$). Reproductive chronology not known. Extraliminally, in the Negev Desert (Israel), one ♀ in early pregnancy was reported at the beginning of Mar and, in the Dead Sea area, 50% of 48 ♀♀ were

lactating in mid-Apr, and one ♀ was still lactating in a cave nearby as late as mid-Jun (Yom-Tov *et al.* 1992).

Conservation IUCN Category: Data Deficient.

Population probably small; suitable habitat might be fragmented, but needs more research to be properly evaluated.

Plecotus gaisleri GAISLER'S LONG-EARED BAT

Fr. Oreillard du Maghreb; Ger. Libysches Langohr

Plecotus gaisleri Benda, Kiefer, Hanak and Veith, 2004. Folia Zool. 53, Monograph 1: 28. Wadi al Kuf, SW Massah, Cyrenaica, Libya.

Taxonomy Populations of *Plecotus* from the Maghreb in NW Africa and Cyrenaica in NE Libya were identified as *P. auritus* and then considered to represent a subspecies of *P. austriacus*. Subsequently, based on morphological evidence, Benda *et al.* (2004c) revised African populations of *Plecotus* and concluded that the Maghrebian and Cyrenaican populations represented subspecies of *P. teneriffae*. They described a new subspecies, *P. t. gaisleri*, based on specimens from Cyrenaica and, pending genetic evidence, tentatively included the Maghrebian population in *P. t. gaisleri* although some differences in colour were observed. In their Appendix 2, however, they referred to the Maghrebian population as *P. t. cf. gaisleri*. Genetic evidence confirmed that the Maghrebian and Cyrenaican populations are distinct (Juste *et al.* 2004). Subsequently, based on both morphological and genetic evidence, Spitzenberger *et al.* (2006) revised the genus *Plecotus*, and concluded that *P. kolombatovici* contained four subspecies of which two occurred in Africa: *P. k. gaisleri* in Cyrenaica and an as yet undescribed subspecies in the Maghreb. More recently, based only on material from Cyrenaica, Mayer *et al.* (2007) raised *gaisleri* to specific status, but did not discuss the relationship of *P. gaisleri* to the Maghrebian population. Therefore, for convenience and pending resolution of this relationship,

in this profile, both populations are treated as *P. gaisleri*, with presumably two subspecies. Synonyms: *aegyptius*, *christiei*. Chromosome number (Tunisia): $2n = 32$; $aFN = 50$ (Baker *et al.* 1974).

Description A very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; five upper and six lower cheekteeth and two upper incisors on each side; ears joined at base, large for a vespertilionid (E: 33–40 mm) and relatively enormous (ca. 92% of FA); dorsal pelage greyish-brown, hairs with basal half dark; face, ears and wings dark; muzzle not inflated behind nostrils. Sexes similar. Pelage dense, soft, slightly woolly; mid-dorsal hairs 7–9 mm. Dorsal pelage greyish-brown; hairs tricoloured with basal half dark rusty-brown, terminal half pale or dark amber depending on humidity of habitat (animals from dry regions are paler) with brown or greyish-brown tip. Ventral pelage pale yellowish-brown or pale greyish-brown; hairs dark greyish-brown with pale yellowish-brown or pale greyish-brown at tip. Face dark brown to dark greyish-brown. Muzzle narrow, not inflated behind nostrils, protuberance above upper eyelid (supraorbital gland) comparatively large, ca. 1.2 mm in diameter (cf. *P. christii*). Ears dark brown to dark greyish-

brown, relatively long (94 [86–99]% of FA and therefore look enormous), inner margins joined by low band at base. Tragus opaque, of medium relative length (46 [42–50]% of E), 6 mm at widest, tapering to blunt point. Eyes relatively large for a microbat. Wing-membranes dark brown to dark greyish-brown; skin over wing-bones moderately darker. Thumb comparatively long (6.1 [5.2–6.8] mm) (cf. *P. christii*). Baculum Y-shaped; lateral arms long, broad, with acute angle between them (Figure 143c).

Skull medium-large for a *Plecotus*, with braincase relatively high, short and broad (braincase width 47–51% of GLS) (Benda *et al.* 2004c). Dorsal profile of forehead region strongly concave for an African *Plecotus* (Figure 142c) (cf. *P. balensis*, *P. christii*). Rostrum relatively long ($C-M^3$: 33–35% of GLS), medium in height and relatively broad (width between canines 68–71% of $C-M^3$). Dentition more robust than in *P. balensis* and *P. christii*. Anterior upper premolar comparatively large (length 0.44–0.54 mm; breadth 0.52–0.62 mm); within tooththrow; canine and posterior premolar well separated.

Geographic Variation There are no profound morphological differences between *P. g. gaisleri* from Cyrenaica and *P. g. cf. gaisleri* from the Maghreb (Benda *et al.* 2004c). These authors observed colour variation in the Maghrebian populations: specimens from more arid desert and semi-desert habitats are paler than those from coastal and montane habitats and, similarly, they are paler than *P. g. gaisleri* from Cyrenaica. Spitzenberger *et al.* (2006) also reported differences in colour but also observed differences in cranial characters. Mean CbL in ♂♂ and ♀♀ respectively: 15.8 and 16.0 mm in *P. gaisleri*; 15.9 and 16.2 mm in *P. g. cf. gaisleri*.

Similar Species The only other vespertilionids in Africa that have ears with inner margins joined are:

Plecotus balensis. Dorsal hairs with basal two-thirds dark brown. Skull with frontal region weakly concave. Rostrum usually relatively shorter and narrower (details in Description). Baculum Y-shaped with obtuse angle between lateral arms. Ethiopia, possibly Eritrea.

P. christii. Ears unpigmented except around tip. Wing-membranes pale, semi-translucent. Muzzle inflated behind nostrils. Skull with frontal region weakly concave; rostrum relatively narrower and usually relatively shorter (details in Description). Baculum Y-shaped with comparatively short lateral arms. NE Sahara (Libya, Egypt, N Sudan).

Barbastella (2 spp.). Ears much shorter (13–18 mm). Only five lower cheekteeth and one upper incisor on each side.

Only one other vespertilionid in Africa has long ears (>28 mm):

Otonycteris hemprichii. Ears with inner margins not joined at base. Only four upper and five lower cheekteeth and one upper incisor on each side.

Distribution In Africa, recorded from the Mediterranean Coastal and Afromontane–Afroalpine BZs in Morocco, Algeria, Tunisia and N Cyrenaica in Libya, and marginally from the Saharan Arid BZ in Morocco, Algeria, Tunisia and Tripolitania (NW Libya) (Aulagnier & Thévenot 1986, Kowalski & RzebiK-Kowalska 1991,

Plecotus gaisleri

Benda *et al.* 2004c, d). Extends from the coast to the NW border of the Sahara (Anti-Atlas, Saharan Atlas, Jebel Nafusa). Old records from Senegal require confirmation and have not been mapped (most probably they have been mislocated).

Habitat Inhabits a variety of open and semi-covered areas – mainly steppes but also agricultural landscapes, lowland basins and mountains. Recorded from sea level to 2630 m in the High Atlas. In the Maghreb, mostly recorded from Morocco and the geographic range covers all the mountain ridges of this country. In Algeria, recorded from the coast to the southern slopes of the Saharan Atlas Mts. In Tripolitania, recorded from three arid places on the Jebel Nafusa. In Cyrenaica, recorded from at least nine localities in an area of ca. 10,000 km² of coastal and montane vegetation.

Abundance Comparatively numerous, although only found in small colonies. Common in both small settlements and large towns.

Adaptations Wing morphology and flight characteristics similar to other *Plecotus*. In summer, roosts by day mainly in rocky cavities and caves, but also in dark areas of minarets, old monuments, ruins, caverns and old houses. Most frequently clings to sides of deep cracks, but also hangs from ceilings. In winter, roosts by day in various spaces in buildings, caves, mines, wells and holes in trees. Found in mixed colonies with *Rhinolophus blasii*. Active all year-round in Algeria, although daily torpor has often been recorded in summer, and undoubtedly occurs in all months.

Foraging and Food Forages at night (and even before sunset in autumn in Algeria; Kowalski & RzebiK-Kowalska 1991), by slow-hawking in parks, over meadows, among rocks with sparse sub-desert vegetation, and over water. Feeds predominantly on medium-sized and large Lepidoptera (mostly Noctuidae), and occasionally on Coleoptera and Diptera (Trujillo 2002).

Echolocation No information.

Social and Reproductive Behaviour In winter, roosts singly or in tight clusters of ca. ten individuals of both sexes. In summer, the sexes segregate; adult ♀♀ roost in maternity colonies of 10–30 adults; they hang separately or in small groups. Mating occurs in autumn; ♂♂ become territorial at this time.

Reproduction and Population Structure Litter-size: one (n = 2). Reproductive chronology not known, probably restricted seasonal monoestry as in *P. teneriffae* (Trujillo 2002). Births occur from end of Apr to mid-May in Cyrenaica, and from May to early Jun in Tunisia (Baker *et al.* 1974). In the Canary Is., 70% of ♀♀ give birth in the main known colony, and most of the young in this colony can fly by mid-Jul (Trujillo 2002). The size of testes is maximal in Sep, which is probably the main mating period.

Predators, Parasites and Diseases Predators occasionally include Barn Owls *Tyto alba* and Pharaoh Eagle-owls *Bubo ascalaphus* (Aulagnier 1989). Ectoparasites include a bat-fly *Nycteribia schmidli* (Diptera: Nycteribiidae), a flea *Nycteridopsylla pentactena* (Siphonaptera: Ischnopsyllidae) and a tick *Carios boueti* (Acari: Argasidae) (Anciaux de Faveaux 1984, Beaucournu & Kowalski 1985).

Conservation IUCN Category: Not Evaluated.
Pesticides threaten populations in agricultural areas.

GENUS *Scotoecus*

Lesser House Bats

Scotoecus Thomas, 1901. Ann. Mag. Nat. Hist., ser. 7, 7: 263. Type species: *Scotophilus albofuscus* Thomas, 1890.

A polytypic genus with, controversially, two, three or four species endemic to sub-Saharan Africa and one endemic to Pakistan and N India (Hill 1974b, Koopman 1994, Simmons 2005). Diagnostic combination of characters (African species only): four or five upper and five lower cheekteeth and one upper incisor on each side (as in *Nycticeinops*, *Otonycteris* and *Scotophilus*); ears relatively short; FA: 28–40 mm; penis very long (9–16 mm); upper canine with anterior surface flattened and grooved; posterior upper molar with three ridges; anterior lower premolar at least two-thirds height of posterior premolar, usually subequal. Skull somewhat flattened; braincase broad; rostrum very broad across lacrymals; dorsal profile (viewed laterally) rising at gentle slope from incisors to lambdoid crest; frontal area slightly convex. Interorbital region broad. Zygomatic arches very slender and weak; usually lost during preparation of skulls. Sagittal and lambdoid crests very weakly developed; helmet slight. Rostral and anterior palatal emarginations very deep. Selected characters of *Scotoecus* are illustrated in Figure 144.

Treated as subgenus of *Nycticeus* (e.g. Ellerman *et al.* 1953, Hayman & Hill 1971), reinstated to generic status by Rosevear (1965) and

retained as a genus by Hill (1974b), Koopman (1993, 1994) and Simmons (2005). In Africa, there are light-winged and dark-winged forms. All light-winged *Scotoecus* are placed in *S. albofuscus* (with *S. a. woodi* as a subspecies) and there are no taxonomical problems associated with this species. In contrast, five dark-winged forms have been named but their status is controversial. Simmons (2005) recognizes three dark-winged species. In contrast, pending resolution of the problems, all dark-winged forms are tentatively considered here to represent one species, *S. hirundo*. The controversies are discussed in the profile of this species.

Both African species are found in woodland savannas; *S. albofuscus* also occurs in some forest habitats.

The African species recognized here are:

S. albofuscus. Wings white, semi-translucent, becoming brownish around edges and near body.

S. hirundo. Wings dark-brown, slightly translucent.

Meredith Happold

Figure 144. African *Scotoecus*. (a) Flight membranes, and bones of wing, hindlimb and tail of *Scotoecus albofuscus* from Malawi. (b) Left ear and tragus of *S. hirundo* from Malawi. (c) Details of left tragus of the same individual. (d) Left tragus of *Scotoecus albofuscus* from Côte d'Ivoire. (e), (f) and (g) Lateral, dorsal and ventral views of skull of *Scotoecus albofuscus woodi* (holotype, BMNH 17.2.1.1, from Malawi).

Scotoecus albofuscus LIGHT-WINGED LESSER HOUSE BAT (GAMBIAN LESSER HOUSE BAT)

Fr. Scotèce à ailes blanche; Ger. Weißflügel-Hausfledermaus

Scotoecus albofuscus (Thomas, 1890). Ann. Mus. Civ. Stor. Nat. Genova 29: 84. Bathurst, Gambia.

Taxonomy Originally *Scotophilus albofuscus*. Synonyms: *woodi*. Subspecies: two of dubious validity (see Geographic Variation). Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and only one upper incisor on each side; ears well separated, short for a vespertilionid (9–15 mm); FA: 29–34 mm; wings white and semi-translucent; penis ca. 9 mm. Sexes apparently similar in colour and size, but data are limited. Pelage soft and dense; mid-dorsal hairs 4–6 mm. Dorsal pelage dark brown, golden-brown or fawn; hairs unicoloured. Ventral pelage slightly paler than dorsal pelage. Head somewhat flattened, muzzle broad, flat with

nostrils opening sideways from small transverse pad. Ears widely separated, comparatively and relatively short for a vespertilionid (40.8 [32–52]% of FA), oval; outer margin with semi-circular antitragus; tip rounded. Tragus short (just over one-third of E), rounded (Figure 144d). Eyes small. Wings white, semi-translucent, becoming brownish with brown venation around edges and close to body; forearms and first, second and third fingers brown, fourth and fifth fingers white. Interfemoral membrane blackish-brown. Calcars long but weak. Penis long (ca. 9 mm).

Skull (Figure 144) as described in Genus *Scotoecus*. Upper incisor fairly long, unicuspid, directed inwards. Upper canine with anterior face flat and conspicuously grooved. Only one upper premolar – anterior premolar apparently always absent (Hill 1974b, Taylor &

van der Merwe 1998). Posterior premolar pointed; in contact with canine; reaching two-thirds to three-quarters height of canine. Posterior upper molar with three ridges (cf. *Scotophilus*). Anterior lower premolar only slightly shorter, and slightly stouter, than the tall, slender posterior lower premolar (cf. *Nycticeinops*). Dental formula: $\frac{1113}{3123} = 30$.

Geographic Variation Two subspecies were recognized, mainly on basis of body and skull measurements, by Hill (1974b) and retained by Koopman (1994) and Simmons (2005). However, analysis of more data than Hill (1974b) had access to suggests that the morphometric differences are slight, but the geographic distributions of the two taxa appear to be very widely separated by the Rainforest BZ in the Congo Basin, and this supports their subspecific status:

S. a. albofuscus: West Africa. FA: 29.7 (29–31) mm, n = 7; GLS: 13.9 (13.1–14.6) mm, n = 4; C–M³: 4.9 (4.7–5.1) mm, n = 8.

S. a. woodi: eastern part of geographical range. FA: 30.1 (29–34) mm, n = 27; GLS: 13.6 (12.7–14.9) mm, n = 21; C–M³: 5.2 (4.9–5.6) mm, n = 21.

Similar Species Three other African vespertilionids have white wings:

Pipistrellus rendalli. Two upper incisors on each side. Penis not extremely long.

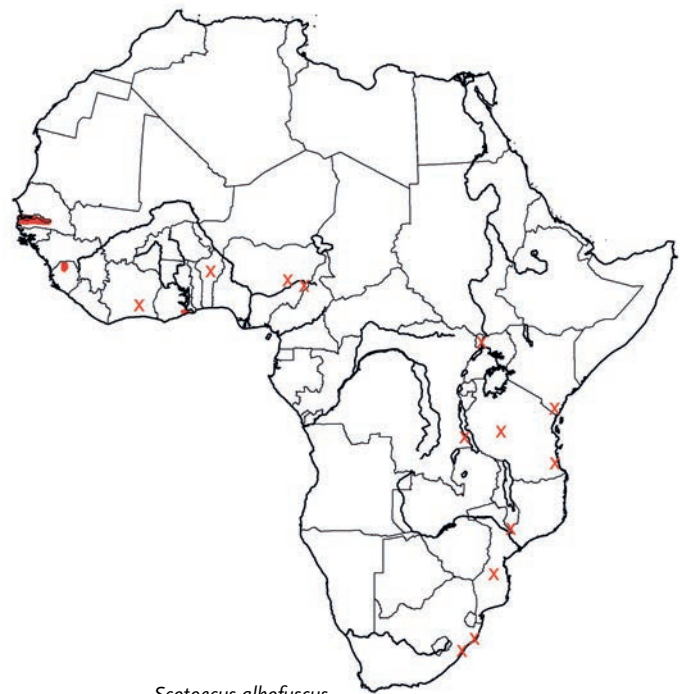

P. tenuipinnis. Two upper incisors on each side. Penis not extremely long.

Glauconycteris gleni. Two upper incisors on each side. Brown reticulation lines on arm-wing. Penis not extremely long.

Note: the wings of some other species, e.g. *Mimetillus moloneyi*, can become very pale after long preservation in alcohol, but these species have two upper incisors on each side.

Distribution Endemic to Africa. Known only from a few scattered localities, mainly in the Sudan Savanna, Guinea Savanna and Zambezian Woodland BZs but with some records in the Rainforest BZ and the Rainforest–Savanna Mosaic in West Africa, and in the Coastal Forest Mosaic BZ. Apparently absent from the Congolian rainforest. Distributed from Gambia to Cameroon, and from Uganda and Kenya to KwaZulu–Natal, but not yet recorded from all countries within this range. Mapped from country checklists (see order Chiroptera), Hill (1974b), Kearney & Taylor (1997), other literature (see below) and museum records.

Habitat In West Africa, recorded from Sudanian woodland savannas including those dominated by *Isoberlinia*; Yola Marsh in Nigeria; and mosaic of grassland and thicket in Shai Hills, Ghana (Rosevear 1965, Grubb *et al.* 1998). No evidence of occurrence in forests in West Africa. Elsewhere, recorded in Zoka Forest, Uganda (Kityo & Kerbis 1996); East African coastal mosaic in Kenya (Whitaker & Mumford 1978); riverine forest with *Hyphaene* palms in S Malawi (R. C. Wood, in Kershaw 1922) and remnants of this forest ca. 80 years later (Happold & Happold 1997); mopane woodland in Mozambique (Smithers & Lobão Tello 1976), and Dune Forest in KwaZulu–Natal (Kearney & Taylor 1997).

Scotoecus albofuscus

Abundance Very rarely collected and considered rare throughout its geographic range, but the use of elevated mist-nets might result in an increase in records (see below).

Adaptations Aspect ratio low; wing-loading medium. Flight fast with very poor manoeuvrability. One bat whose flying abilities were tested could not fly around a 3.5×3.5 m room by banking, and did not attempt to turn by stalling-and-twisting (M. Happold unpubl.). Mr R. C. Wood (in Kershaw 1922) noted that these bats roosted ‘among the leaves of low *Hyphaene* palms in forest, where they appear to be moderately numerous, though rarely seen’.

Foraging and Food Based on wing morphology and the flying characteristics of one individual, predicted to forage by moderately fast-hawking mainly in open spaces moderately high above ground and above canopies of trees. This, and the difficulty of catching this species at its day-roosts, might explain why *S. albofuscus* is rarely collected: it might be caught more often in elevated mist-nets in the future. The stomachs of three individuals in Kenya contained mainly Hemiptera and Coleoptera, with some Lepidoptera, Diptera and other insects (Whitaker & Mumford 1978).

Echolocation No comparable information available but one call is illustrated in Monadjem *et al.* (2010).

Social and Reproductive Behaviour Several may be taken together nestling down among the leaves (R. C. Wood in Kershaw 1922).

Reproduction and Population Structure At 16°32'S (Chiromo, Malawi), one ♀ was post-lactating in early Apr (M. Happold unpubl.). At 28°17'S (St Lucia, KwaZulu–Natal, South Africa), a newly caught ♀ gave birth to twins in late Nov (Kearney & Taylor 1997).

Predators, Parasites and Diseases Ectoparasites include a bat-fly *Basilia robusta* (Diptera: Nycteribiidae) and mites *Spinturnix walkeri* (Acari: Spinturnicidae) and *Notoedres* sp. (Acari: Sarcoptidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Data Deficient.

Scotoecus hirundo DARK-WINGED LESSER HOUSE BAT (SWALLOW-LIKE LESSER HOUSE BAT)

Fr. Scotèce hironnelle; Ger. Schwarzflügel-Hausfledermaus

Scotoecus hirundo (de Winton, 1899). Ann. Mag. Nat. Hist., ser. 7, 4: 355. Gambaga, Ghana.

Taxonomy Originally *Scotophilus hirundo*. Synonyms: *albigula*, *artinii*, *falabae*, *hindei*. Subspecies: uncertain (see Geographic Variation). The taxonomy of dark-winged *Scotoecus* is controversial. Ellerman *et al.* (1953) placed all dark-winged *Scotoecus* in *S. hirundo*. Hill (1974b) revised the genus and divided African dark-winged forms into *S. hirundo* with no subspecies, and *S. hindei* with subspecies *S. h. hindei* and *S. h. albigula* (the latter having more massive canines and cheekteeth). A collection of one *S. h. hindei* and one *S. h. albigula* from Malawi (identified by J. E. Hill on basis of craniodental measurements) appeared to provide evidence of sympatry and, consequently, *albigula* was raised to specific status (Happold *et al.* 1987), a conclusion followed by Ansell & Dowsett (1988). However, a larger collection of eight ♂♂ and 11 ♀♀ from Malawi showed that differences in C–M³ and M³–M³ were correlated with sex, the ♂♂ having more massive teeth than the ♀♀: consequently, Happold & Happold (1997) followed Koopman (1965, 1975, 1993) and Robbins (1980) who placed all dark-winged *Scotoecus* in *S. hirundo*. Robbins (1980) recorded sexual dimorphism in dark-winged *Scotoecus* from Benin and Ghana (♂♂ larger than ♀♀), and also analysed Hill's measurements (Hill 1974b) to show that his sample of *S. hirundo* was comprised mostly of ♀♀ (14 of 17) and his sample of *S. hindei* was mostly ♂♂ (eight of nine). Taylor & van der Merwe (1998) conducted a principal component analysis of seven cranial characters of 19 dark-winged *Scotoecus* to test Koopman's (1993) hypothesis that *hindei*, *albigula* and *hirundo* are synonymous. They found that five *hirundo* from Cameroon, Uganda and Ethiopia, four *falabae* from Cameroon, four *hindei* from Ethiopia and Uganda plus one from Malawi, four other specimens referred to as *S. cf. hindei* from Malawi, and one *albigula* from Malawi, separated into five clusters, suggesting that *S. hirundo*, *S. hindei* and *S. albigula* merited specific status, and that the specimens referred to as *S. cf. hindei* could not be grouped with any of the above species. Sex was not taken into consideration in this study. Cotterill (2001e) measured FA and eight craniodental parameters of 11 female and two male dark-winged specimens from Zambia and, based on differences in skull proportions, concluded that one ♀ represented *S. hindei* and the

others *S. albigula*. The specimen he referred to *S. hindei* was larger and outside (albeit sometimes very marginally) the ranges of specimens referred to *S. albigula*, in the following measurements and ratios: C¹–C¹, C¹–C¹ as percentage of GLS, M³–M³, M³–M³ as percentage of GLS and C–M³. Although these differences indicate the possible presence of two species, the sample size is too small for statistical analysis. Pending a revision of dark-winged forms that takes sexual dimorphism into consideration, all dark-winged forms are provisionally treated here as *S. hirundo*. Chromosome number (Kenya, as *S. hindei*): 2n = 30; aFN = 50 (Nagorsen *et al.* 1976).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four or five upper cheekteeth, five lower cheekteeth and only one upper incisor on each side; ears well separated and short for a vespertilionid (9–14 mm); FA: 28–40 mm; wings blackish-brown; penis extremely long (14–16 mm); anterior lower premolar at least two-thirds height of posterior premolar, usually only slightly shorter. Sexes similar in colour; ♂♂ on average slightly larger in some body measurements and with more massive teeth, longer upper tooththrow and wider M³–M³ (Robbins 1980, M. Happold unpubl.). Pelage soft, dense, with no sheen; mid-dorsal hairs 4–6 mm. Dorsal pelage chocolate brown, or medium to pale sepia brown; hairs unicoloured (Malawi) or with basal half off-white, terminal half sepia brown (West Africa). Ventral pelage grey, beige, greyish-white or pale beige: chest sometimes paler. Head somewhat flattened; muzzle broad, flat, dark brown, almost naked. Nostrils opening sideways from small transverse pad. Ears widely separated, comparatively and relatively short for a vespertilionid, oval; tip rounded. Tragus relatively short (41.9 [38–46]% of E); somewhat hatchet-shaped, anterior margin strongly concave; posterior margin with smooth, obtuse angle just above mid-height, tip rounded (Figure 144c; Malawi). Eyes very small. Wings and interfemoral membrane dark brown, slightly translucent. Penis extremely long, 14–16 mm, ca. 25–30% of HB.

Skull as described in Genus *Scotoecus*. Less flattened than in *S. albofuscus*. Upper canine with anterior surface flat and shallowly

grooved. Anterior upper premolar usually present (at least on one side) but minute, fully displaced lingually, sometimes loose and possibly easily lost. Posterior upper premolar pointed, in contact with canine and reaching two-thirds to three-quarters height of canine. Posterior upper molar with three ridges (cf. *Scotophilus*). Anterior lower premolar at least two-thirds height of posterior lower premolar, usually only slightly shorter (cf. *Nycticeinops*). Sexual dimorphism in craniodental characters is illustrated by differences in M^3-M^3 – in Benin and Ghana, ♂♂: 6.6 (6.3–6.8) mm, $n = 11$; ♀♀: 6.4 (5.8–6.6) mm, $n = 19$ (Hill 1974b in Robbins 1980). In Malawi, ♂♂ 7.7 (7.6–7.8) mm, $n = 6$; ♀♀ 7.3 (7.1–7.6) mm, $n = 10$ (M. Happold unpubl.). Dental formula: $\frac{1113}{3123} = 30$ or $\frac{1123}{3123} = 32$.

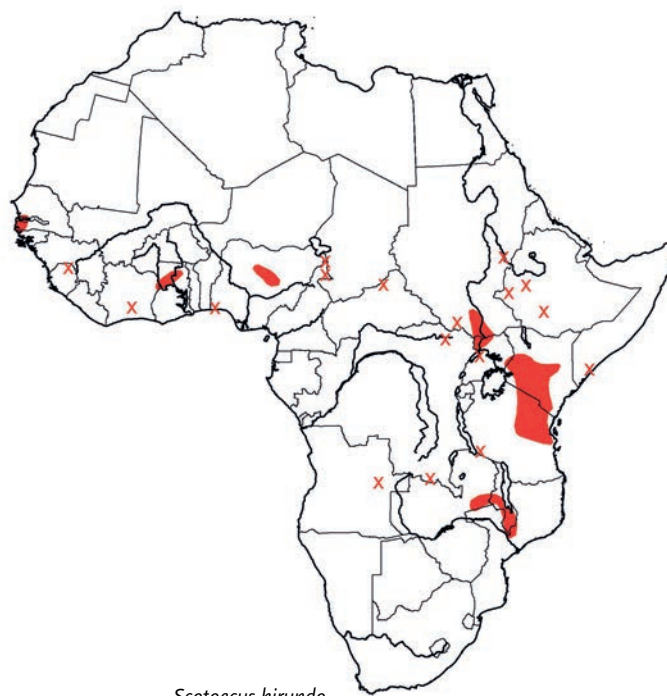

Geographic Variation Koopman (1994) recognized four subspecies, *S. h. hirundo* (Senegal to Benin, and possibly to Ethiopia), *S. h. falabae* (Nigeria and Cameroon), *S. h. hindei* (Southern Sudan and Somalia to SE DR Congo) and *S. h. albigula* (Kenya to Angola). However, the status and distribution of these forms is uncertain (see Taxonomy). A preliminary survey of FA, C– M^3 and M^3-M^3 measurements (made by different people) suggests that there is geographic variation, with an increase in size (in both sexes) from Ghana/Benin (Robbins 1980), to Sudan/Ethiopia, to Kenya/Tanzania, to Malawi. For example, in ♂♂, mean FA for these areas (in the above order) are 33.4 ($n = 11$); 33.6 ($n = 5$); n. d.; 35.4 ($n = 18$). Similarly, mean C– M^3 : 5.1 ($n = 11$); 5.2 ($n = 6$); 5.5 ($n = 9$), 6.0 ($n = 8$). Similarly, mean M^3-M^3 : 6.6 ($n = 11$), 6.6 ($n = 4$); Kenya/Tanzania n. d.; 7.7 ($n = 6$). West African specimens have bicoloured dorsal pelage, cf. unicoloured in Malawi.

Similar Species Only one other dark-winged vespertilionid has only one upper incisor on each side and FA: <41 mm:

Nycticeinops schlieffeni. Usually lighter (5.5 [4–9] g). FA: 28–35 mm. Dorsal pelage cinnamon, fawn or greyish-fawn; ventral pelage slightly to considerably paler, whitish or pure white. Tragus more pointed (Figure 144c). Penis 5.6–6.2 mm. Anterior lower premolar ca. half size of posterior premolar. Upper canine with anterior surface rounded and not grooved.

Note: *Mimetillus molonyi* also has an extremely long penis, but differs in having very short wings, a dorsoventrally flattened skull and two upper incisors on each side.

Distribution Endemic to Africa. Widespread south of the Sahara, mainly in the Sudan Savanna, Guinea Savanna, Somalia–Masai Bushland and Zambezi Woodland BZs, but with some records from the outer edges of the Rainforest–Savanna Mosaics and in the Coastal Forest Mosaic BZ. Recorded from most countries from Senegal to Sudan, Ethiopia and S Somalia, and southwards (mainly on eastern side of continent) to S Angola and S Malawi. Mapped from country checklists (see order Chiroptera), Hill (1974b), other literature and museum records. Apparently avoids the Congolian rainforest. In Angola, recorded from Lac Calundo and from the ‘Cunene Region’ in SW Angola (Crawford-Cabral 1989): the latter locality is not mapped. Subsequent records (Thorn & Kerbis Peterhans 2009) show that this species is more widespread in Uganda than the map

Scotoecus hirundo

indicates. Furthermore, Monadjem *et al.* (2010) have mapped five localities between ca. 19°S and ca. 25°S in S Mozambique that are not mapped here.

Habitat Found in open woodlands in West Africa (with one record from Lagos in the rainforest zone) (Rosevear 1965); woodlands and deciduous thicket and bushland in the east, and both wetter and drier miombo woodland vegetation zones in the south. In Malawi, has been found in miombo woodland, mosaic of farmland and woodland, relict rainforest, riverine woodland, gardens, villages and towns, at 100–1500 m (Happold & Happold 1987).

Abundance Uncertain. Rarely collected in West Africa (Grubb *et al.* 1998) and in most parts of its geographic range, but commonly recorded in Malawi (Happold & Happold 1997).

Adaptations Aspect ratio low; wing-loading medium. Flight fast to very fast, and agile with moderate manoeuvrability. Turns by banking (minimum radius of turn >25 and <50 cm; none of eight individuals carried out a stall-and-twist turn while under observation in captivity. Individuals could fly across a 1×1×1 m enclosure, but very rarely completed a full circuit (11 bats, 10 flights each; M. Happold unpubl.). By day, known to roost under the corrugated iron roofs of huts and houses, but natural day-roosts are not known. Becomes torpid during day at ambient temperatures of 21–24°C in Malawi. Predicted mean maximum urine concentration is comparatively very high (4550 mOsmol/kg). Captive bats, fed on winged termites and offered water twice/day, drank irregularly (mean drinks/day over a ten-day period, ranged from 0.1 to 0.5 in four individuals; Happold & Happold 1988). All of the above adaptations refer to bats from Malawi. At Masalani (02°18'S, 38°07'E) near Kibwezi in Kenya, numbers of *S. hirundo* were comparatively low during the long dry season (May–Oct), and there was a build-up of subcutaneous fat prior to this period. These

observations led O'Shea and Vaughan (1980) to suspect emigration from Masalani to places that receive rainfall during May–Oct (e.g. the highlands of W Kenya or the coast).

Foraging and Food Forages by moderately fast-hawking. Light-tagged bats ($n = 4$, Malawi) foraged in open spaces, above canopies of trees or over grassland, usually more than 5 m above ground, and often as high as ca. 25 m. They also came as low as 2 m to fly between the trunks of tall eucalyptus trees in a plantation. They foraged at high speed with long, level flights interspersed with spectacularly acrobatic swerving, up and down as well as sideways (M. Happold unpubl.). Diet not known.

Echolocation Search-phase call-shape (Malawi) in open spaces (a) very shallow linear FM and (b) curvilinear steep/shallow FM; these calls are sometimes emitted in alternation (7 bats, flying in open after release; M. Happold unpubl.) (Figure 145). For calls of type (a): intensity high; end-frequency 30–34 kHz; bandwidth 2–4 kHz; call-duration mostly 5–6 ms. End-frequencies of adjacent calls sometimes vary by ca. 2 kHz. For calls of type (b): intensity high, end-frequency 32–34 kHz; bandwidth ca. 6–7 kHz; call-duration mostly 5–6 ms. When calls alternate between types (a) and (b), the end-frequency of (a) is often 2–3 kHz lower than the end-frequency of (b). Approach-phase calls are firstly curvilinear steep/shallow FM sweeps of bandwidth up to ca. 15 kHz, and then steep FM/QCF of greater bandwidth. Calls emitted while close to ground in cluttered environments are steep FM/QCF sweeps; intensity high start-frequency up to 70 kHz; end-frequency 33–40 kHz (17 bats, tethered or as released). Characteristic frequencies (Anabat terminology, based on peak-frequencies) of sequences of steep FM/QCF sweeps emitted by ♀♀ were 37.6 (35–40) kHz (10 bats, 16 sequences), and by ♂♂ were 35.1 (35–37) kHz (6 bats, 10 sequences) with the exception of 39 kHz emitted by one ♂. The difference in characteristic frequency apparently largely reflects the sexual dimorphism in size exemplified by this species, with the larger ♂♂ echolocating at lower frequencies. A sequence including search-phase, approach-phase and 'feeding buzz' calls is shown in Figure 27 and a sequence of search-phase calls showing alternation between different call-shapes and frequencies is shown in Figure 145.

Figure 145. Sonogram of a sequence of search-phase calls emitted by *Scotoecus hirundo* from Malawi, showing alternation between calls of different call-shape and frequency (M. Happold unpubl.).

Social and Reproductive Behaviour No information.

Reproduction and Population Structure Litter-size: 2 ($n = 3$). At 02°18'S (Masalani, inland Kenya), the reproductive chronology is restricted seasonal monoestry with births in Nov (O'Shea & Vaughan 1980). At 15–16°S in Malawi, the chronology is also restricted seasonal monoestry with early pregnancy in Sep ($n = 1$); pregnancy in Oct ($n = 1$); birth in Nov ($n = 1$); 29 of 29 adult ♀♀ lactating Nov–Jan; volant young with unfused epiphyses Jan–Mar ($n = 28$); 4 of 4 adult ♀♀ post-lactating Feb–Mar; and 49 of 49 ♀♀ palpably not pregnant Apr–Jun. From Sep–Jan, 81% of 16 adult ♂♂ had abdominal testes. From Feb–May, 88% of 25 ♂♂ had large scrotal testes. These data suggest that mating may occur in ca. May, followed by sperm storage or reproductive delay until ca. late Aug, but this needs confirmation.

Predators, Parasites and Diseases Ectoparasites include a bed-bug *Cacodmus sparsilis* (Hemiptera: Cimicidae) (Kock *et al.* 1998b) and a flea *Echidnophaga aethiops* (Siphonaptera: Pulicidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

GENUS *Scotophilus*

House Bats

Scotophilus Leach, 1821. Trans. Linn. Soc. Lond. 13: 69, 71. Type species: *Scotophilus kuhlii* Leach, 1821.

A polytypic genus with 12 species recognized by Simmons (2005) and two species described subsequently by Goodman *et al.* (2005, 2006). Of these 14 species, six occur in Africa, three on Madagascar and one on Réunion I. in the Indian Ocean, and four in Asia. Diagnostic combination characters (African species): four upper and five lower cheekteeth and one upper incisor on each side (as in *Otonycteris*, *Nycticeinops* and *Scotoecus*); ears relatively short; FA: 41–88 mm; penis relatively short; anterior upper molar with two ridges. *Scotophilus* are robust and heavy-bodied, with brown dorsal pelage and yellow, yellowish, white or whitish ventral pelage and dark wings. Tragus long and tapering. Thumb with swollen pad at base. Testes posterior to anus in at least three species. Adult ♀♀ of *S. dinganii*, *S. leucogaster* and *S. viridis* (the only species for which published data are available) have one pair of functional nipples. However, juvenile *S. dinganii* of both sexes have two pairs of rudimentary nipples, one of which disappears later (Verschuren 1957); no information for other species. Skull with well-developed sagittal crest and occipital helmet. Braincase not rising above plane of rostrum so dorsal profile of skull (viewed laterally) is mostly a gentle slope from front to back with a very shallow concavity in the forehead region. Jaws and dentition robust. Upper incisor long, unicuspid; upper canine long. Upper molars unusual – anterior and middle molars with concave surfaces, indistinct ridges and a worn appearance; posterior molar very short

with only two ridges (cf. three in *Nycticeinops* and *Scotoecus*). Dental formula: $^{1113}/_{3123} = 30$. Some external and craniodental characters of *Scotophilus* are shown in Figure 146.

The taxonomy of *Scotophilus* is very controversial and is undergoing further revision. Hayman & Hill (1971) recognized three species: *gigas*, *nigrita* (including *dinganii*, *nux* and other forms) and *leucogaster* (including *viridis* and other forms). Robbins (1978) showed that *nigrita* was the prior synonym of *gigas*, and that bats previously referred to as *nigrita* should be called *dinganii*. Based on multivariate analysis, Robbins *et al.* (1985) recognized six species in Africa: *S. dinganii*, *S. leucogaster*, *S. nigrita* (formerly known as *S. gigas*), *S. nucella*, *S. nux* and *S. viridis*, and restricted *S. borbonicus* and *S. robustus* to Réunion and Madagascar, respectively. Koopman (1994) recognized only three African species: *S. borbonicus* (including *viridis*), *S. leucogaster* (including *dinganii*, *nucella* and *nux*) and *S. nigrita*, but he subsequently recognized five African species: *S. dinganii*, *S. leucogaster* (including *nucella*), *S. nigrita*, *S. nux* and *S. viridis* (Koopman 1993). Additional taxonomic problems are discussed in the species profiles. Here we follow Robbins *et al.* (1985) as does Simmons (2005).

Since this profile was submitted, Jacobs *et al.* (2006) indicated that a cryptic sibling species of *S. dinganii* lives sympatrically with *S. dinganii* in KwaZulu–Natal and Zambia (see Appendix). The cryptic form, as yet not formally described but tentatively named *S. mhlangani* (Jacobs

Figure 146. African *Scotophilus*. Flight membranes, and bones of wing, hindlimb and tail (e.g. *Scotophilus dinganii*). Left ear and tragus (e.g. *S. dinganii*). Skull (e.g. *S. nux*; ZFMK 2003. 1058).

et al. 2007), is said to echolocate with calls having peak frequencies 44.3 ± 0.9 kHz (according to Jacobs *et al.* 2007) or 42.6 ± 1.6 kHz (according to Jacobs & Barclay 2009). In contrast, *S. dinganii* in the same location emits lower frequencies (33.7 ± 1.8 kHz) (Jacobs & Barclay 2009). The cryptic species is smaller (FA: 48 [46–52] mm, $n = 17$), differs genetically (Jacobs *et al.* 2006) and karyotypically (Eick *et al.* 2007), and occupies a different ecological niche (Jacobs & Barclay 2009). However, Monadjem *et al.* (2010) consider that this form represents *S. viridis* (according to the original description of this species) and that the name *S. mhlangani* is a *nomen nudum*. *Scotophilus mhlangani* is undoubtedly a *nomen nudum*, but until further evidence clarifies the taxonomic status of this form and its relationships with *S. dinganii*, *S. viridis* and also *S. leucogaster*, it is not mentioned in any species profile here.

In Africa, two species are found only in rainforest, one in rainforest and savanna and three mainly or entirely in savanna habitats.

Some of the six African species can be recognized by their habitats and characters (see Table 28). However, *S. leucogaster* and *S. viridis* are best distinguished by the following discriminant functions in which $x > 0$ (positive) indicates *S. leucogaster*, $x < 0$ (negative) indicates *S. viridis* (V. Van Cakenberghe unpubl.).

North of Equator:

$$x = (0.226 \times \text{GLS}) + (1.235 \times \text{IoB}) + (0.608 \times \text{MW}) + (0.709 \times \text{C-M}_3) - 21.2$$

South of Equator:

$$x = (0.712 \times \text{GLS}) + (1.118 \times \text{IoB}) + (0.590 \times \text{MW}) + (2.802 \times \text{C-M}_3) - 43.3$$

Similarly, *S. leucogaster* and *S. dinganii* can be distinguished by the following discriminant function in which $x > 0$ (positive) indicates *S. dinganii*, $x < 0$ (negative) indicates *S. leucogaster*.

Throughout ranges of both species:

$$x = (0.484 \times \text{CbL}) - (0.741 \times \text{IoB}) - (0.455 \times \text{MW}) + (1.063 \times \text{C-C}) - 6.57$$

All measurements in mm. Abbreviations:

GLS = Greatest length of skull. Measured from most posterior part of skull to the base of the upper incisor.

CbL = Condylbasal length of skull. Measured from the posterior of an exoccipital condyle to the base of the upper incisor.

IoB = Interorbital breadth.

MW = Mastoid width.

C-M₃ = Length of lower toothrow. Measured from base of the lower canine to the base of the posterior lower molar.

C-C = Width across the upper canines. Measured at the base of the teeth.

The six species found in mainland Africa are presented in alphabetical order.

Victor Van Cakenberghe & Meredith Happold

Table 28. Key to the African mainland species in the genus *Scotophilus*. *Scotophilus dinganii*, *S. leucogaster* and *S. viridis* are best distinguished by the discriminant functions in Genus *Scotophilus*. Note separation of *S. leucogaster* and *S. viridis* into populations north and south of the Equator.

| FA (mm) | Ventral pelage | Dorsal pelage | Habitat | Species |
|--------------|---|---|---|---|
| 82.3 (78–88) | Yellow, yellowish or white | Various shades of dark brown suffused with yellow | Mainly Savannas; also Rainforest and Coastal Forest Mosaic | <i>S. nigrata</i> |
| 56.5 (53–61) | Dark brown to reddish-orange | Rusty-brown to blackish-brown | Rainforest | <i>S. nux</i> |
| 51.3 (49–53) | Dark brown to reddish-orange | Dark rusty-brown to blackish-brown | Rainforest | <i>S. nucella</i> |
| 53.3 (47–60) | Pale yellow, bright yellow or orange-yellow; not tinged with brown. In SW Arid zone, sometimes off-white (as in <i>S. leucogaster</i>) | Sepia brown, greenish-brown, greyish-brown or reddish-brown | Savannas and Rainforest–Savanna Mosaics; marginally in Rainforest | <i>S. dinganii</i> |
| 49.9 (44–58) | Pure white to medium brown; never yellowish | Pale to medium brown; never tinged with yellow or green | Savannas and Rainforest–Savanna Mosaics | <i>S. leucogaster</i>
North of Equator |
| 45.5 (41–50) | Always yellowish (pale to medium yellow), sometimes with brownish tinge | Yellowish-brown, greenish-brown to darker orange-brown | Savannas and Rainforest–Savanna Mosaics; marginally in rainforest | <i>S. viridis</i>
North of Equator |
| 47.5 (43–51) | Pure white to medium brown; perhaps sometimes yellowish | Pale to medium brown, not tinged with yellow or green | Not rainforest | <i>S. leucogaster</i>
South of Equator |
| 45.9 (42–50) | Pale grey or pale brown; perhaps sometimes yellowish | Greenish-brown to medium brown | Not rainforest | <i>S. viridis</i>
South of Equator |

Scotophilus dinganii YELLOW-BELLIED HOUSE BAT

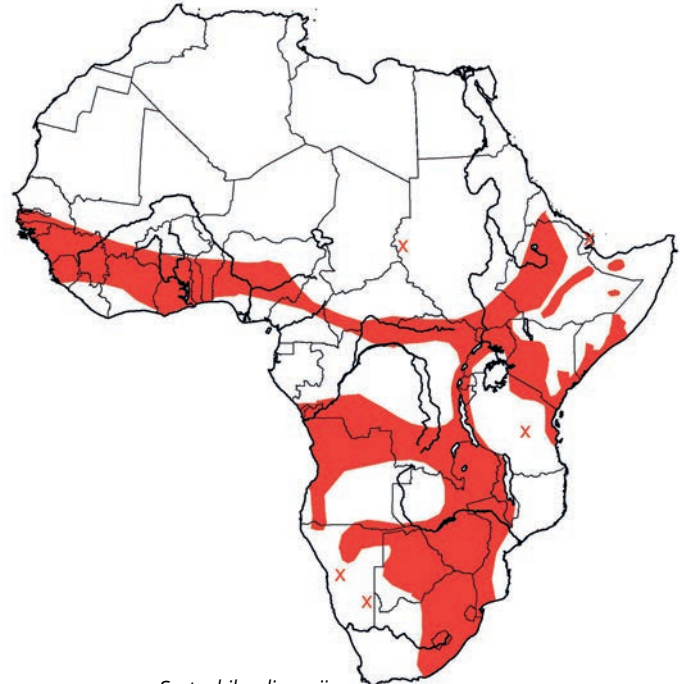

Fr. Scotophile à ventre jaune; Ger. Gelbbäuchige Hausfledermaus

Scotophilus dinganii (A. Smith, 1833). S. Afr. Quart. J. 2: 59. Between Port Natal [= Durban, South Africa] and Dalgoo Bay [= Maputo, Mozambique].

Taxonomy Originally *Vespertilio dinganii*. Synonyms: *colias*, *herero*, *planirostris*, *pondoensis*. Subspecies: uncertain (see Geographic Variation). This species was widely referred to as *S. nigrita* until Robbins (1978) showed that *S. nigrita* was a senior synonym of the very large *S. gigas* and that the next available name for the smaller species was *S. dinganii*. As *S. nigrita*, this species was considered to include *leucogaster* by Koopman (1975), but not by Rosevear (1965) nor (as *S. dinganii*) by Schlitter *et al.* (1980). The specific status of *S. dinganii* has been accepted without dispute since the review of African *Scotophilus*, based on multivariate analysis, by Robbins *et al.* (1985). Chromosome number (South Africa): $2n = 36$; $aFN = 52$. Four pairs metacentric, five pairs submetacentric and eight pairs acrocentric chromosomes. X = small acrocentric; Y = small metacentric (15 ♀♀; 16 ♂♂) (Schlitter *et al.* 1980). In specimens from Somalia, $aFN = 50$ and there are eight pairs metacentric and nine pairs acrocentric (the smallest with secondary constriction); X = medium submetacentric; Y = small telocentric (Ruedas *et al.* 1990).

Description Small, heavily built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, short for a vespertilionid (11–22 mm); FA: 47–60; dorsal pelage greenish-brown, greyish-brown or reddish-brown; ventral pelage yellow to orange (never tinged with brown) or off-white in the South-West Arid BZ. Best distinguished from *S. leucogaster* by discriminant function (see Genus *Scotophilus*). Sexes similar in colour, ♀♀ on average slightly larger in body measurements. Pelage smooth, soft and sleek; mid-dorsal hairs 6–7 mm. Dorsal pelage sepia brown, greenish-brown, greyish-brown or reddish-brown; hairs paler at base. Ventral pelage pale yellow, bright yellow or orange-yellow, not tinged with brown; sometimes off-white in the South-West Arid BZ. Ears comparatively and relatively short for a vespertilionid (25–37% of FA), widely separated; inner margin strongly convex; outer margin almost straight. Tragus moderately long, tapering to bluntly rounded tip: anterior margin concave (Figure 146). Eyes small. Wings and interfemoral membrane uniformly dark brown, semi-translucent. Testes posterior to anus. Adult ♀♀ with one pair of functional nipples; juveniles of both sexes with two pairs of rudimentary nipples (one disappears later) (Verschuren 1957). Skull and dentition as described for the genus.

Geographic Variation Uncertain. No subspecies were recognized by Robbins *et al.* (1985), who tabulated means and standard variations of FA and seven cranial parameters for population samples from 13 widespread localities. In contrast, Koopman (1994) treats *colias*, *dinganii*, *herero* and *pondoensis* (and four other forms) as subspecies of *S. leucogaster*, and Simmons (2005) treats *colias*, *herero* and *pondoensis* as subspecies of *S. dinganii* but comments that subspecies are poorly defined. The form *herero*, which occurs in the South-West Arid BZ, has ventral pelage pale yellow to off-white with or without yellow on flanks.

Scotophilus dinganii

Similar Species Four other African *Scotophilus* have FA: <61 mm (Table 28, p. 673):

Scotophilus leucogaster. Best distinguished by discriminant functions, see Genus *Scotophilus*. North of Equator, ventral pelage white or whitish, sometimes tinged with brown, not tinged with yellow (south of Equator, pelage of both species is sometimes similar).

S. viridis. FA almost always shorter (45.5 [41–50] mm). Skull shorter (GLS: 17.0 [15.6–18.0] mm).

S. nucella. Dorsal pelage dark rusty-brown to blackish-brown; ventral pelage dark brown to reddish-orange. Rainforest.

S. nux. Dorsal pelage dark rusty-brown to blackish-brown; ventral pelage dark brown to reddish-orange. Rainforest.

Distribution Endemic to Africa. Widespread south of the Sahara and recorded from most biotic zones and most countries, from Gambia to Eritrea, Djibouti and Somalia and southwards to Namibia and South Africa. However, this species is known only around the edges of the Rainforest BZ, there are only a few records in the arid Horn of Africa and in the South-West Arid BZ, and there are no records from the South-West Cape BZ. The distribution gaps in the Somalia–Masai Bushland and Zambezian Woodland BZs are unexplained. Mapped mainly from Robbins *et al.* 1985.

Habitat Found in most habitats south of the Sahara. Most records are from woodland savannas (including Sudanian undifferentiated woodlands, *Isoberlinia* woodlands, miombo woodland)

and various bushland and thicket savannas. Also lives in rainforest habitats around the edges of the Rainforest BZ (but apparently not in the interior of the Congolian rainforest), in rainforest–savanna mosaics, and in riverine, coastal and montane forests. Thrives in farmlands and suburban areas.

Abundance Common in many areas; probably common throughout most of geographic range.

Adaptations Aspect ratio medium; wing-loading medium (M. Happold unpubl.). Flight fast and agile; cannot fly slowly; manoeuvrability poor; can take off from ground. Turns by banking (minimum radius of turn >50 cm), and by stalling-and-twisting (but not in confined spaces). Able to fly across a 1×1×1 m enclosure, but not able to complete a full circuit (6 bats, 10 flights each; M. Happold unpubl.). Scuttling, head first, up and down, over horizontal, sloping and vertical surfaces, is efficient although not as fast as in molossids. Roosts by day in small holes in trees and wooden lamp-posts (including nests of barbets [Capitonidae] and woodpeckers [Picidae]), and in crevices within hollow trees. Also commonly roosts in narrow crevices and crannies in buildings (both occupied and deserted), particularly under eaves and roofs of corrugated iron, and in crannies in thatch. This may largely explain the abundance of this species in farmlands and suburbia. Scuttles from landing and take-off sites to the nooks in which it roosts. Prefers to rest on sloping or horizontal surfaces, but sometimes clings to vertical surfaces. Tolerates high temperatures under iron roofs (Kingdon 1974). Not known to roost with other species of bats. In Malawi, at 20–21 °C, does not become torpid by day (Happold & Happold 1988). Seasonal fluctuations in abundance at particular localities were observed in Sudan (Thomas & Hinton 1923) and East Africa (Kingdon 1974). In the Shire Highlands, Malawi, captures/month were higher in the wet season (Nov–Feb) than in Mar–Jun and Sep–Oct (no data for Jul–Aug; M. Happold unpubl.). In Zimbabwe, absent from the plateau above 1200 m during the colder months (Smithers & Wilson 1979). Does not hibernate in South Africa (Rautenbach *et al.* 1988). Drinks, on the wing, from pools, streams and dams, and captive bats, fed winged termites, drank every day; predicted mean maximum urine concentration is comparatively low (2851 mOsmol/kg) (Happold & Happold 1988).

Foraging and Food Forages by moderately fast-hawking in moderately uncluttered spaces above canopies, in clearings and over fields (M. Happold unpubl.). Sometimes forages near lights, and sometimes comes into houses at night. Although individuals come to streams and dams to drink, there is no evidence, from echolocation calls, that they pursue insects flying near the surface. Not known to forage as high as some molossids and emballonurids, and often forages closer to trees and as low as ca. 2 m from the ground. Foraging is characterized by long, straight or gently banked flights (during which prey may be captured), and abrupt acrobatic swerves and spectacular dives in pursuit of prey (M. Happold unpubl.). Foraging begins soon after sunset and bats often have full stomachs before it is dark (Kingdon 1974). Foraging is not deterred by rain (M. Happold unpubl.). Apparently feeds mainly on beetles, but other flying insects are taken opportunistically (Kingdon 1974, Fenton 1985, Aldridge & Rautenbach

1987). In Kenya, three stomachs contained Coleoptera (65% by volume), Hemiptera (13%), Orthoptera (13%) and Lepidoptera (5%) (Whitaker & Mumford 1978).

Echolocation Search-phase calls (Malawi and South Africa) are high intensity, very shallow linear FM sweeps and smooth or angular steep/shallow FM sweeps of broader bandwidth, both with end-frequencies 28–35 kHz (Aldridge & Rautenbach 1987, Taylor 2000, M. Happold unpubl.) (Figure 118k, m). As prey is approached, the calls become broader in bandwidth, steeper and the shallow FM component becomes shorter and is lost just before the feeding-buzz commences. There are striking similarities between the calls of *S. dinganii* and those of the molossids *Tadarida pumila* and *T. condylura*, which also forage in uncluttered spaces.

Social and Reproductive Behaviour Very little known. Smithers & Wilson (1979) observed congregations of hundreds foraging where termites were swarming in Zimbabwe. Sightings of two individuals flying close together (tailing one another) have been reported, and it is common to capture a ♂ and ♀ side-by-side in a mist-net (E. C. J. Seamark pers. comm.). Of 93 bats mist-netted in Malawi (excluding those captured while emerging from day-roosts), 66 were netted singly, six were netted in pairs, 14 were netted with another of same sex, and six were netted in groups comprised of two ♂♂ and one ♀ (M. Happold pers. obs.). Occasionally roosts singly but usually roosts in groups of up to ca. 20; several groups sometimes roost under one roof but in different parts (Smithers 1983, M. Happold pers. obs.). In KwaZulu–Natal, South Africa, roosts singly or in groups of 2–10, and some roosts are occupied for at least eight years (Taylor, P. 1998). Group composition not known. Kingdon (1974) described the behaviour of a ♀ which gave birth, in captivity, to twins. During the first week, the ♀ licked the young, sheltered them with one wing, and sometimes squeaked. The young remained attached to the nipples until the third night, after which time they occasionally roosted beside her or climbed over her. When the young were a few days old, there were some prolonged bursts of squeaking in which both mother and young participated.

Reproduction and Population Structure Litter-size: usually two, sometimes one, occasionally three. Reproductive chronology at 15–16°S in Malawi is restricted seasonal monoestry with births in Nov–Dec, lactation Nov–Jan, post-lactation Jan–Feb (no data Jul–Sep) (Happold & Happold 1990a and unpubl.). Adult ♂♂ with enlarged scrotal testes and others with abdominal testes were present Oct–Mar (no data Apr–Sep). This chronology is also manifested at 22–31°S in South Africa (E. C. J. Seamark pers. comm.). In Uganda, 2 of 3 ♀♀ in Feb–Mar were pregnant and two young were recorded in May (Okia 1987), but Okia's suggestion that there are two breeding seasons is based on combined data from Zimbabwe, DR Congo and Uganda, which is not valid evidence of polyoestry. At 02°18'S (Masalani, near Kibwezi, Kenya), births were recorded during Nov and Mar–Apr during a year-round study on a resident population (O'Shea & Vaughan 1980), but it was not stated that these bats were polyoestrous, and the percentage of ♀♀ that gave birth during each of these periods was not given. Possibly *S. dinganii* is polyoestrous near the Equator, but this needs confirmation.

Predators, Parasites and Diseases In Zimbabwe, *Scotophilus* (species uncertain) are taken by Bat Hawks *Macheiramphus alcinus* (Fenton *et al.* 1978). Ectoparasites include bed-bugs *Cacodmus sparsilis* and *Aphrania* cf. *barys* (Hemiptera: Cimicidae); a flea *Chiropteropsylla brockmani* (Siphonaptera: Ischnopsyllidae); a bat-fly *Basilia glabra* (Diptera: Nycteribidae); and a mite *Spinturnix walkeri* (Acari: Spinturnicidae) (Whitaker & Mumford 1978, Wolton *et al.* 1982, Beaucournu & Kock 1989, 1996, Kock *et al.* 1998b).

Conservation IUCN Category: Least Concern.

Widespread and common; one of the species that roosts in occupied houses and has adapted well to semi-urban and agricultural environments.

Meredith Happold

Scotophilus leucogaster WHITE-BELLIED HOUSE BAT

Fr. Scotophile à ventre blanc; Ger. Weißbäuchige Hausfledermaus

Scotophilus leucogaster (Cretzschmar, 1830). In: Rüppell, Atlas Reise Nördl. Afr., Zool. Säugeth., p. 71. Brunnen Nedger [Nedger Well, = Bir Nedger], Kordofan, Sudan.

Taxonomy Originally *Nycticejus leucogaster*. Synonyms: *altilis*, *damarensis*, *flavigaster*, *murinoflavus*. There are taxonomic problems, much controversy and much confusion associated with the names *leucogaster*, *borbonicus* and *viridis* and also *nigrita* and *dinganii* (see Genus *Scotophilus*). Here we follow Robbins *et al.* (1985) who, based on multivariate analysis, consider *leucogaster* to be specifically distinct from *viridis*, and include *damarensis* in *S. leucogaster* rather than in *S. viridis*. Because of the problems associated with the names, and also because *S. leucogaster* is not always easily distinguished from *S. viridis*, data in literature and museums pertaining to *S. leucogaster* is sometimes reported under other names (e.g. *S. borbonicus*, *S. nigrita* and *S. viridis*), and data pertaining to other species (e.g. *S. viridis*) is sometimes reported under *S. leucogaster*. Consequently it is difficult to assess the identity of the specimens reported in the literature. In this profile, information is restricted to material considered to represent *S. leucogaster* by Robbins *et al.* (1985), or by V. Van Cakenberghe or C. B. Robbins based on examination of new material and/or its distribution, or by re-examination of material mentioned in Robbins *et al.* (1985). Subspecies: two. Chromosome number (Namibia and Burkina): 2n = 36; aFN = 50 (Ruedas *et al.* 1990 and M. Volleth pers. comm., respectively).

Description Small, heavily-built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, short for a vespertilionid (11–17 mm); FA: 43–58 mm; dorsal pelage sepia brown to pale brown; ventral pelage white to dirty medium brown (not tinged with yellow except perhaps sometimes in southern Africa). Best distinguished from *S. viridis* and *S. dinganii* by discriminant functions (see Genus *Scotophilus*). Sexes similar. Pelage smooth, soft and sleek; mid-dorsal hairs 6–8 mm.

Dorsal pelage medium sepia brown to pale brown (not tinged with green, orange or yellow); hairs unicoloured or becoming slightly paler towards base. Ventral pelage, north of Equator, white, off-white, very pale brown (beige) or dirty medium brown (not tinged with yellow); throat and chest sometimes paler than abdomen; chin sometimes almost naked and dark brown. Ventral pelage, south of Equator, might be tinged with yellow in some individuals, especially in the eastern part of the geographic range, but this needs confirmation. Pelage colouration can be faded by alcohol, rendering identification of preserved material, based on colour of ventral pelage, unreliable – originally yellowish *S. viridis* can look like whitish *S. leucogaster*. Ears comparatively and relatively short for a vespertilionid (24–37% of FA), widely separated; inner margin strongly convex; outer margin almost straight. Tragus tapering to bluntly rounded tip; anterior margin concave. Eyes small. Wings and interfemoral membrane uniformly dark brown, semi-translucent. Testes posterior to anus. Adult ♀♀ with one pair of functional nipples.

Skull and dentition as described for the genus. C–M³ slightly longer and more robust than in *S. viridis*. Posterior median projections of palate slightly more developed than in *S. viridis*, and projecting ventrally below the pterygoids. According to Robbins *et al.* (1985), the pterygoids are comparatively longer, and narrower between their posterior tips, than in *S. viridis*. However, these differences are very vague and might be the result of damage to the pterygoid bones during preparation of the skulls. Interorbital breadth: 4.9 (4.3–5.9) mm, n = 250; mastoid width: 11.6 (10.4–12.8) mm, n = 212; lower C–M₃: 7.0 (6.5–7.7), n = 254 (cf. *S. viridis*).

Geographic Variation Based on its discontinuous distribution, two subspecies are recognized by Robbins *et al.* (1985):

- S. l. leucogaster*. FA: 49.9 (44–58) mm; GLS: 18.3 (16.5–20.3) mm. North of Equator (Mauritania to Ethiopia and NW Kenya).
S. l. damarensis. FA: 47.5 (43–51) mm; GLS: 18.3 (17.3–19.9) mm. South of Equator (SW Kenya, Angola, W Zambia, S Malawi and southwards to Namibia, Botswana, S Mozambique and possibly NE South Africa).

Similar Species Four other African *Scotophilus* have FA: <61 mm (Table 28, p. 673):

- Scotophilus viridis*. Best distinguished by discriminant functions, see Genus *Scotophilus*.
S. dinganii. Best distinguished by discriminant function, see Genus *Scotophilus*. North of Equator, ventral pelage yellow to orange, not tinged with brown (south of Equator, pelage of both species is sometimes similar).
S. nucella. Dorsal pelage dark rusty-brown to blackish-brown; ventral pelage dark brown to reddish-orange. Rainforest.
S. nux. Dorsal pelage dark rusty-brown to blackish-brown; ventral pelage dark brown to reddish-orange. Skull longer (GLS: 19.6–23.0 mm). Rainforest.

Distribution Endemic to Africa. Recorded mainly from the Sudan Savanna, Guinea Savanna and Zambezian Woodland BZs, but with scattered records in the Sahel Savanna BZ, Northern and Eastern Rainforest–Savanna Mosaics, Somalia–Masai Bushland BZ, Coastal Forest Mosaic BZ and South-West Arid BZ (Namib Desert). Recorded from Mauritania, Senegal, Gambia, NW Guinea-Bissau and Sierra Leone (but not Liberia) to Sudan and NW Ethiopia, and southwards to Uganda and Kenya. Also recorded from Angola, Namibia, N Botswana, W Zambia, NW Zimbabwe, S Malawi, S Mozambique and possibly Kruger N. P., South Africa. Re-examination of specimens from Chiromo and Nsanje in S Malawi, identified as *S. viridis* by Robbins *et al.* (1985), indicates that they represent *S. leucogaster*. Specimens

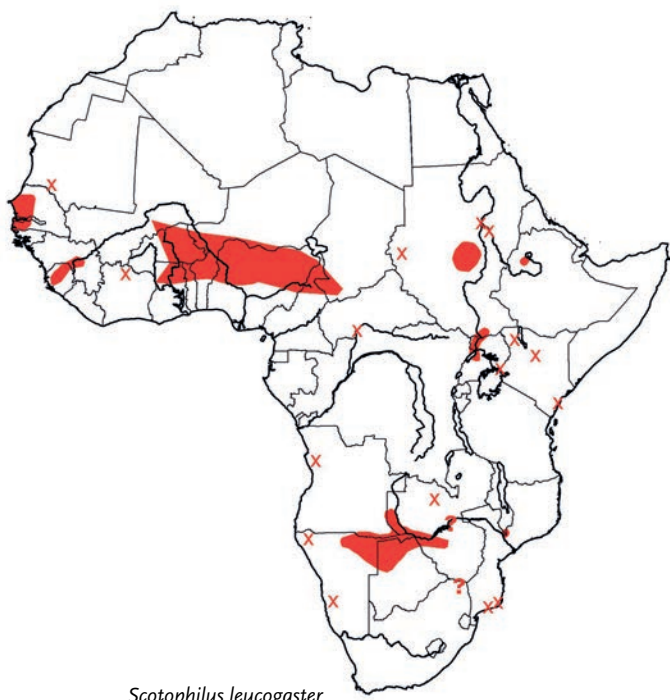

from Punda Milia in Kruger N. P. include large and small animals, and specimens without yellow in their ventral pelage as well as yellow-bellied specimens: this material needs re-examination to confirm if both *S. leucogaster* and *S. viridis* occur in Kruger N. P. Small *Scotophilus* with white bellies and yellow bellies occur in the Mana Pools N. P. of NW Zimbabwe, and are presumed to represent two species by Fenton *et al.* (1998b): skulls from this locality have not been analysed, but circumstantial evidence (including echolocation) suggests both forms represent *S. viridis*.

Habitat In West Africa, recorded from riverine woodland along rivers in shrub savanna in Park du W, Niger (Poché 1975), over grassland between riverine forest and Guinea savanna, and under mango trees in Nigeria (Bergmans 1977a). South of the Equator, recorded from mopane and miombo woodland, riverine forests and woodlands, open grasslands, flood-plains and pans, with many of the localities near rivers or marshes such as the Okavango Swamp in Botswana (Smithers 1971), the Cuanza R. in Angola, the Zambezi R. and its tributaries in Zambia (Ansell 1978) and the Sengwa, Lutope and Shana rivers in Zimbabwe (Barclay 1985). Seasonal fluctuations in abundance have been recorded in the Sahel Savanna BZ in Burkina (Koch-Weser 1984) and in S Mali (Meinig 2000), suggesting exploitation of drier areas in wet season and contraction or migration into wetter habitats in the dry season. In contrast, there is no evidence of migration in Sudan (Kock 1969a, as *S. nigrita*).

Abundance Uncertain. The most commonly mist-netted species at Sengwa (i.e. Sengwa Wildlife Research Area, Zimbabwe) (Barclay 1985).

Adaptations In Mali, roosts by day under dried leaves of *Borassus* palms (L. Granjon pers. comm.). In Sudan, roosts by day in holes in baobab trees *Adansonia* (Cretzschmar 1828–30), and under iron roofs of houses where mid-day temperatures can reach over 40 °C (Kock 1969a). At Sengwa, roosts by day in hollow mopane trees *Colophospermum mopane* (Fenton 1983, Barclay 1985). Roost-fidelity was observed in Sudan. In contrast, radio-tracked individuals regularly switched roosts at Sengwa (Fenton 1983). In Sudan, individuals were lethargic and flew clumsily unless the temperature was 34 °C or higher (Kock 1969a).

Foraging and Food Radio-tracked and light-tagged individuals foraged by moderately fast-hawking, 2–20 m above ground, in uncluttered open spaces above trees and over grasslands, and in moderately uncluttered spaces between tree trunks and tree-canopies (Fenton 1983, Barclay 1985). Foraging has been observed in mopane, miombo and riverine woodlands, and over flood-plains and the grassy edges of rivers. Foraging begins when the bats leave their roosts soon after dusk, and their stomachs are soon filled. Radio-tracked bats flew up to 3 km away from their roosts to find food and/or water. On bright moonlit nights, activity is reduced and the bats stay near or under trees. In Sudan, foraging begins soon after sunset and the bats often have full stomachs within an hour: subsequently, bouts of foraging are interspersed between pauses for digestion and rest. In contrast, at Sengwa, foraging only occurs during the first hour of the night, and the avoiding of open spaces on moonlit nights, are ways of reducing predation from aerial predators (Fenton *et al.* 1977,

Scotophilus leucogaster

Barclay 1985). At Sengwa, *S. leucogaster* feeds mainly on Coleoptera, Lepidoptera and Hemiptera, but also on Hymenoptera, Orthoptera, Homoptera, Neuroptera and Diptera (Barclay 1985, Fenton *et al.* 1977, as *S. viridis*). There is some evidence that Coleoptera and Hemiptera are particularly important in the wet season, and that Lepidoptera only comprise a major part of the diet in the dry season. Possibly, the bats are more selective in what they eat during the wet season when insects are more abundant. Captive bats ate geckoes and the carcasses of mice (Kock 1969a).

Echolocation Search-phase call-shape (Sengwa): steep/shallow FM. End-frequency 34 kHz; maximum call-duration: 10 ms (5 bats; Fenton & Bell 1981, as *S. viridis*).

Social and Reproductive Behaviour At Sengwa, day-roosts in hollow mopane trees contained 1–9 individuals of unrecorded age and sex (mean 4.6, $n = 15$ counts as the bats emerged; Fenton 1983).

Reproduction and Population Structure Litter-size: two (Barclay 1985). At ca. 18°S (Sengwa Wildlife Research Area, Zimbabwe), births were observed in Nov and Dec (Barclay 1985).

Predators, Parasites and Diseases In Mali, Barn Owls *Tyto alba* feed on *S. leucogaster* when mice *Mastomys huberti* are scarce: both *T. alba* and *S. leucogaster* roost among the leaves of palms *Borassus aethiopicus* (L. Granjon pers. comm.). At Sengwa, *Scotophilus* (species uncertain) are preyed on by Bat Hawks *Macheiramphus alcinus* (Fenton

et al. 1978). Ectoparasites (in Nigeria) include a mite *Spinturnix scotophili* (Acari: Spinturnicidae) (Dusbábek & Bergmans 1980).

Conservation IUCN Category: Least Concern.

Scotophilus nigrita GIANT HOUSE BAT

Fr. Grand scotophile africain; Ger. Riesen-Hausfledermaus

Scotophilus nigrita (Schreber, 1774). Die Säugethiere 1: 171. Senegal.

Taxonomy Originally *Vespertilio nigrita*. Widely referred to as *S. gigas* until Robbins (1978) showed that *nigrita* was the senior synonym of *gigas*, and that bats previously referred to as *nigrita* should be called *dinganii*. Synonyms: *alvenslebeni*, *gigas*. Subspecies: two. Chromosome number: not known.

Description A large, heavily built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, medium-sized for a vespertilionid (20–24 mm); FA: 78–83 mm; dorsal pelage brown; ventral pelage yellow, yellowish or white. Largest African vespertilionid. Sexes similar in colour; forearms of ♀♀ usually longer than those of ♂♂. Pelage mid-dorsal hairs 6–7 mm. Dorsal pelage blackish-brown, sepia brown, greenish-brown, rusty-brown or greyish-brown suffused with yellow; hairs unicoloured. Ventral pelage pale yellow to pale yellowish-grey (one individual white). Ears medium-sized but relatively short for a vespertilionid (28–31% of FA, $n = 4$), blackish-brown, widely separated; inner margin strongly convex with lobe at base; outer margin fairly straight with semi-circular fleshy antitragus. Tragus tapering to bluntly rounded tip; anterior margin concave. Wings and interfemoral membrane blackish-brown.

Skull with very well developed sagittal crest and occipital helmet. Canines particularly strong.

Geographic Variation Two subspecies are recognized (De Vree 1973b):

S. n. nigrita: Savannas of West Africa and Sudan. Almost always larger (FA: 85.9 [83–88] mm, $n = 5$; GLS: 30.7 [30.0–32.1] mm, $n = 6$).

S. n. alvenslebeni: Savannas of eastern and southern Africa. Almost always smaller (FA: 80.5 [77–84] mm, $n = 8$; GLS: 29.3 [28.5–30.4] mm, $n = 8$).

Similar Species None: all other African *Scotophilus* are much smaller (FA: <61 mm) (Table 28, p. 673):

Distribution Endemic to Africa. Known only from a few scattered localities, in the Sahel Savanna, Sudan Savanna, Guinea Savanna and Rainforest BZs (in Senegal, Côte d'Ivoire, Ghana, Togo, Nigeria), in the Sudan Savanna BZ (in Sudan), and in the Zambezian Woodland BZ and Coastal Forest Mosaic BZ (in SE DR Congo, Kenya, Tanzania, Malawi, Zimbabwe and Mozambique. A record from Botswana (Cotterill 1996a, Taylor 2000) is erroneous (F. P. D. Cotterill pers. comm.). Distribution appears disjunct, but this species is probably difficult to record and the gaps are likely to be artefacts. Mapped from Robbins *et al.* (1985), Cockle *et al.* (1998) and Grubb *et al.*

Scotophilus nigrita

(1998). According to Monadjem *et al.* (2010), also recorded from Komatipoort and Malelane in South Africa (not mapped here).

Habitat Recorded from relatively dry woodland savannas including Guinea, Sudan, Sahel and miombo woodland savannas, but often in the vicinity of rivers and riverine forests (R. C. Wood in Kershaw 1922, Dorst 1959, Smithers 1983). Also recorded from one locality in drier, semi-deciduous forest in Ghana (Grubb *et al.* 1998), from a woodland and riverine forest mosaic in Tanzania (Cockle *et al.* 1998), and from Lagos in the rainforest zone (Rosevear 1965), but precise details of this locality are not known.

Abundance Uncertain. Very rarely encountered and usually considered very rare.

Adaptations In Sudan, found under the corrugated iron roof of a house where mid-day temperatures sometimes reached over 40 °C (Kock 1969a); *Scotophilus leucogaster* was captured while emerging from the same roost several evenings earlier. In Malawi, near confluence of Ruw and Shire Rivers, one was found in a hollow, dead *Hyphaene* palm, one was shot over the bank of a river and another over a village (R. C. Wood's data with specimens in BMNH). In Zimbabwe, one was found in a house. One was mist-netted over an almost dry river in Togo (De Vree 1973b) and the Tanzanian specimen was mist-netted over a pool (Cockle *et al.* 1998).

Foraging and Food Foraging behaviour: no information but predicted to forage high above the ground (D. Kock pers. comm.). Kock (1969a) suggested these bats are carnivorous, but this was based on the observation that captive individuals of the smaller species, *S. leucogaster*, ate geckos and bodies of bats, and his observation that insects are scarce in Sudan during the dry season. Freeman (1984) notes that the occlusal cusp pattern of the molar teeth of *S. nigrita* is that of a strictly carnivorous bat but, on the other hand, other characters of the teeth suggest that their function is to crush rather than to slice, and therefore she suggests that *S. nigrita* is insectivorous.

Scotophilus nucella ROBBINS'S HOUSE BAT

Fr. Scotophile de Robbins; Ger. Robbins Hausfledermaus

Scotophilus nucella Robbins, 1983. Ann. Kon. Mus. Mid. Afr., Zool. Wetensch. and Mus. Roy. Afr. Centr. Sc. Zool., 237: 19.

[Publication has Dutch and French titles.] 1 mile N Nkawkaw, Eastern Region, Ghana.

Taxonomy Considered a subspecies of *S. leucogaster* by Koopman (1993, 1994), but considered distinct by Simmons (2005). Its status was not reviewed by Robbins *et al.* (1985). Synonyms: none. Chromosome number: not known.

Description Small, heavily built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, short for a vespertilionid (15–16 mm); FA: 49–53 mm; dorsal pelage dark rusty-brown to blackish-brown; ventral pelage slightly paler to reddish-orange. Sexual dimorphism not apparent from limited data. Pelage soft, sleek. Dorsal pelage dark rusty-brown to blackish-brown; hairs unicoloured or with paler base. Ventral pelage slightly paler, dark brown to reddish-orange. Ears comparatively and relatively short for a vespertilionid (ca. 29% of FA), widely separated, dark brown; inner margin strongly convex with lobe at base; outer margin fairly straight with semi-circular, fleshy antitragus. Tragus tapering to pointed tip; anterior margin concave. Wings and interfemoral membrane sepia brown.

Skull typical of genus; braincase relatively inflated (cf. *S. leucogaster*); sagittal crest forming a conspicuous helmet.

Geographic Variation None recorded.

Similar Species Four other African *Scotophilus* have FA: <61 mm (Table 28, p. 673):

*Scotophilus nucella*

Scotophilus nux. Larger (FA: 56.4 [53–61] mm; GLS: 21.1 [19.6–23.0] mm, CbL: 19.0 [18.4–19.6] mm).

S. dinganii. Dorsal pelage (except in South-West Arid BZ) greenish-brown, greyish-brown or reddish-brown; ventral pelage pale yellow, yellow, orange, not tinged with brown. Savannas and rainforest-savanna mosaics; marginally in rainforest.

S. leucogaster. Dorsal pelage pale to medium brown; ventral pelage white, whitish, medium brown, sometimes yellowish. North of Equator in savannas and rainforest-savanna mosaics; south of Equator, various zones but not rainforest.

S. viridis. North of Equator, dorsal pelage yellowish-brown, greenish-brown or orange-brown; ventral pelage pale to medium yellow, sometimes tinged with brown. Savannas, riverine forests and coastal forests.

Distribution Endemic to Africa. Recorded from the Rainforest BZ in Côte d'Ivoire (J. Fahr pers. comm.) and Ghana, and from the Eastern Rainforest-Savanna Mosaic in Uganda (Robbins 1983). Predicted to occur in other rainforest areas of West, Central and East Africa (Robbins 1983). Occurs sympatrically with *S. nux* in Ghana and, based on their representation in collections made over a period of years, the two species occur in ca. equal numbers in the area of the type locality (Robbins 1983). *Scotophilus nucella* is sympatric with *S. nux* and *S. dinganii* in Uganda.

Habitat Rainforest.

Abundance Uncertain. When described, only ten specimens were known: two from each of three localities near Nkawkaw, Ghana, three from Oda, Ghana (collected on two occasions) and one from Budongo Forest, Uganda (Robbins 1983). Subsequently, apparently only collected from Côte d'Ivoire (J. Fahr pers. comm.; details not given).

Remarks After the description by Robbins (1983), hardly any references have been made to this species.

Conservation IUCN Category: Data Deficient.

Known from nine specimens from Ghana and one from Uganda, housed in three collections (CM, ROM, USNM) when described in 1984, and apparently rarely collected since. Consequently its range is poorly known and its population trend is not known.

Scotophilus nux NUT-COLOURED HOUSE BAT

Fr. Scotophile noisettes; Ger. Nussfarbene Hausfledermaus

Scotophilus nux Thomas, 1904. Ann. Mag. Nat. Hist., ser. 7, 13: 208. Efulen, Cameroon.

Taxonomy Synonyms: none. Often considered to be a subspecies of *S. dinganii* (as *S. nigrita*) (e.g. Hayman & Hill 1971) and sometimes a subspecies of *S. leucogaster* (e.g. Koopman *et al.* 1978, Koopman 1994). Recognized as a distinct species by Robbins *et al.* (1985) on basis of multivariate analysis of FA and seven cranial parameters and, following these authors, recognized as distinct by Simmons (2005). Chromosome number (Cameroon): 2n = 36; aFN = 50. The non-differentially stained karyotype is identical with that of *S. dinganii* from Somalia except that in *S. nux* the autosomal pair bearing the secondary constriction is distinctly larger, the X is larger and the Y is smaller (Ruedas *et al.* 1990).

Description Small, heavily built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, short for a vespertilionid (15–21 mm); FA: 53–60 mm; dorsal pelage rusty-brown to blackish-brown; ventral pelage slightly paler. Sexes similar. Pelage smooth, sleek and glossy; mid-dorsal hairs 6–7 mm. Dorsal pelage rusty-brown, dark rusty-brown or blackish-brown; hairs unicoloured. Ventral pelage slightly paler, dark brown to reddish-orange. Ears comparatively and relatively short for a vespertilionid (23–29% of FA), widely separated, dark brown; inner margin strongly convex with lobe at base; outer margin fairly straight with semi-circular fleshy antitragus. Tragus tapering to bluntly rounded tip; anterior margin concave. Wings and interfemoral membrane blackish-brown. Skull and dentition as in Figure 146.

Geographic Variation None recorded.

Similar Species Four other African *Scotophilus* have FA <61 mm (Table 28, p. 673):

Scotophilus nucella. Smaller (FA: 51.3 [49–53] mm; CbL: 17.3 [17.1–17.5] mm).

S. dinganii. Dorsal pelage (except in South-West Arid BZ) greenish-brown, greyish-brown or reddish-brown; ventral pelage pale yellow, yellow, orange, not tinged with brown. Savannas and rainforest–savanna mosaics; marginally in rainforest.

S. leucogaster. Dorsal pelage pale to medium brown; ventral pelage white, whitish, medium brown, sometimes yellowish. Skull shorter (GLS: 16.5–20.3 mm). North of Equator in savannas and rainforest–savanna mosaics; south of Equator, in various habitats but not rainforest.

Scotophilus nux

S. viridis. Smaller (FA: 45.9 [41–50] mm; GLS: 17.1 [15.6–18.3] mm). Dorsal and ventral pelage paler. Savannas and riverine and coastal forests.

Distribution Endemic to Africa. Recorded from the Rainforest BZ and the Northern and Eastern Rainforest–Savanna Mosaics from Sierra Leone, Côte d'Ivoire, Ghana, SE Nigeria and Cameroon, and from NW DR Congo to W Kenya. The gap between Cameroon and NW DR Congo probably reflects insufficient sampling in this area. The gap between SW Ghana and Calabar in Nigeria needs investigation. Map based on Robbins *et al.* (1985).

Habitat Lowland rainforest and clearings in the rainforest. Recorded in swamp forest in Tâi N. P., Côte d'Ivoire (Fahr & Kalko 2011).

Abundance Uncertain.

Remarks In Sierra Leone, roosts in small groups in roofs of houses; quite common in built-up areas; commonly has twins (Grubb *et al.* 1998). Also roosts in hollow trees. Two ♀♀, each with one large foetus, were recorded in Mar in DR Congo (Lang & Chapin 1917b).

Conservation IUCN Category: Least Concern.

Comparatively widespread; not known to be declining.

Scotophilus viridis GREEN HOUSE BAT

Fr. Petit scotophile africain; Ger. Grünliche Hausfledermaus

Scotophilus viridis (Peters, 1852). Reise nach Mossambique, Säugethiere, p. 67. Mozambique I., 15° S, Mozambique.

Taxonomy Originally *Nycticejus viridis*. Synonyms: *nigritellus*. There are taxonomic problems, much controversy and much confusion associated with the names *leucogaster*, *borbonicus* and *viridis*, and also *nigrita* and *dinganii* (see genus *Scotophilus*). Here we follow Robbins *et al.* (1985) who, based on multivariate analysis, consider *viridis* to be specifically distinct from *leucogaster*, and do not include *damarensis*, nor consider *viridis* to be a synonym of *borbonicus*. Because of the problems associated with the names, and also because *S. viridis* is not always easily distinguished from *S. leucogaster*, data in literature and museums pertaining to *S. viridis* is sometimes reported under other names (e.g. *S. borbonicus*, *S. leucogaster*), and data pertaining to other species (e.g. *S. leucogaster*, *S. dinganii*) is sometimes reported under *S. viridis*. Consequently it is very difficult to assess the identity of the specimens reported in the literature. In this profile, information is restricted to material considered to represent *S. viridis* by Robbins *et al.* (1985), or by V. Van Cakenberghe or C. B. Robbins based on examination of new material and/or its distribution, or by re-examination of material mentioned in Robbins *et al.* (1985), with the exception of some data for Malawian bats that have not been checked by these authors (see Distribution). Subspecies: possibly two. Chromosome number (South Africa): 2n = 36; aFN = 54 (Schlitter *et al.* 1980). Ruedas *et al.* (1990) report 2n = 36; aFN = 50 for *S. viridis* from Namibia but, based on distribution, these specimens represent *S. leucogaster*.

Description Small, heavily built microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; four upper and five lower cheekteeth and one upper incisor on each side; ears separated, short for a vespertilionid (13–18 mm); FA: 41–50 mm; dorsal pelage variable shades of brown; ventral pelage always yellowish north of Equator (cf. *S. leucogaster*) and usually yellowish (but sometimes whitish or pale brown, without any yellow) south of the Equator. Best distinguished from *S. leucogaster* by discriminant functions (see Genus *Scotophilus*). Sexes similar. Pelage smooth, soft and sleek; mid-dorsal hairs ca. 6 mm. Dorsal pelage (north of Equator) yellowish-brown, greenish-brown to darker orange-brown; hairs with paler base. Ventral pelage (north of Equator) pale to medium-yellow, sometimes with brownish tinge, never whitish; hairs unicoloured. Dorsal pelage (south of Equator) greenish-brown to medium-brown; hairs with paler base. Ventral pelage (south of Equator) pale to medium yellow (unlike *S.*

leucogaster) or whitish, pale grey or pale brown (as in *S. leucogaster*). In alcohol, the yellow colour can be faded leading to confusion with *S. leucogaster*. Ears comparatively and relatively short for a vespertilionid (28–37% of FA), widely separated, dark brown; inner margin strongly convex; outer margin almost straight. Tragus moderately long, tapering to bluntly rounded tip; anterior margin concave. Eyes small. Wings and interfemoral membrane uniformly dark brown, semi-translucent. Testes posterior to anus. Adult ♀ ♀ with one pair of functional nipples.

Skull and dentition as described for the genus. According to Robbins *et al.* (1985), compared to *S. leucogaster*, the posterior median projections of the palate are not as well developed and do not project ventrally much below the pterygoids and, usually, the pterygoids are relatively shorter but wider between their posterior tips. These differences, however, are fairly vague or might be the result of damage to the pterygoid bones during preparation of the skulls. Interorbital breadth: 4.5 (3.9–5.0) mm, n = 150; mastoid width: 10.6 (9.6–11.4) mm, n = 141; C–M₃: 6.5 (5.9–7.2) mm, n = 149 (cf. *S. leucogaster*).

Geographic Variation No subspecies are recognized by Robbins *et al.* (1985) and Simmons (2005) but small differences in size suggest there might be two subspecies:

S. v. viridis: East Africa, south-central and southern Africa. FA: 46.8 (42–50) mm, n = 82; GLS: 17.2 (16.2–18.0) mm, n = 60; C–M³: 5.8 (5.4–6.6) mm, n = 60.

S. v. nigritellus: West Africa to Central African Republic, and probably Sudan and Ethiopia. FA: 45.0 (41–48) mm, n = 81; GLS 16.8 (15.6–17.8) mm, n = 69; C–M³: 5.7 (5.3–6.1) mm, n = 78.

However, the validity of these subspecies is not completely supported by biometrical data, and the affinities of specimens from Sudan and Ethiopia need further investigation.

Similar Species Four other African *Scotophilus* have FA: <61 mm (Table 28, p. 673):

Scotophilus leucogaster. Best distinguished by discriminant functions, see Genus *Scotophilus*.

S. dinganii. FA almost always longer (53.3 [47–60] mm). Skull longer (GLS: 20.5 [18.3–23.5] mm).

S. nucella. Dorsal pelage dark rusty-brown to blackish-brown; ventral pelage dark brown to reddish-orange. Rainforest.

S. nux. Larger (FA: 56.5 [53–61] mm; GLS: 21.1 [19.6–23.0] mm). Dorsal and ventral pelage darker. Rainforest.

Distribution Endemic to Africa. Although records are scattered, probably occurs throughout the Guinea Savanna BZ and wetter parts of the Sudan Savanna BZ from Gambia and Senegal to S Sudan and W Ethiopia (with some records in the Northern Rainforest–Savanna Mosaic). Also occurs in the Afromontane–Afroalpine BZ, Coastal Forest Mosaic BZ and Zambezian Woodland BZ in Kenya, Tanzania (including Mafia I.; Kock & Stanley 2009), Zambia, Malawi, Zimbabwe, Mozambique and South Africa. The identity of white-bellied and yellow-bellied bats from Mana Pools N. P., NW Zimbabwe, reported respectively as *S. borbonicus* and *S. 'viridis'* by Fenton *et al.* (1998b), has not been confirmed by analysis of skulls but circumstantial evidence (including echolocation) suggests that both forms represent *S. viridis*. Re-examination of specimens from Chiromo and Nsanje in S. Malawi, identified as *S. viridis* by Robbins *et al.* (1985), indicates they represent *S. leucogaster*. Yellow-bellied specimens from Lengwe N. P. and Chiromo, Malawi, identified as *S. viridis* by Happold *et al.* (1987) and Happold & Happold (1997), have not yet been re-examined to confirm their identity. Material from Mana Pools N. P. in NW Zimbabwe also needs re-examination to confirm the identification of *S. 'viridis'* reported by Fenton *et al.* (1998b). Many, possibly all, of the disjunctions in the distribution might reflect insufficient sampling.

Habitat Not well known. In the Shai Hills (Ghana), recorded mostly in mosaic of grassland and *Zanthoxylum*–*Capparis* thickets, but also amongst savanna trees, and near a waterhole in grassland (Decher 1997). In Central African Republic, captured near bank of river with interrupted strips of gallery forest (Schlitter *et al.* 1982). In Tanzania, reported from

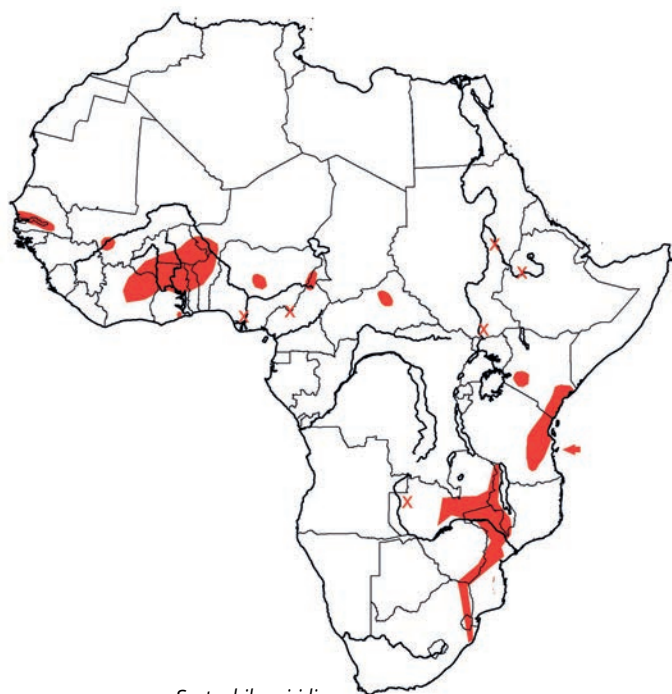

seven of 16 patches of coastal forest investigated by Cockle *et al.* (1998). In Malawi, recorded from miombo woodland dominated by *Brachystegia*, *Kirkia* and *Sterculia*, mostly near streams. Possibly also inhabits riverine woodland in the Lower Shire Valley but this needs confirmation (see Distribution). Appears to prefer wetter habitats than *S. leucogaster*.

Abundance Uncertain. Uncommonly recorded in Malawi (Happold & Happold 1997). Fairly common in some collections from elsewhere.

Adaptations Aspect ratio low; wing-loading medium (Aldridge & Rautenbach 1987, M. Happold unpubl.). Flight fast and agile; manoeuvrability moderate; able to take off from ground. Turns by banking (minimum radius ca. 50 cm) and by stalling-and-twisting. Able to fly across a 1×1×1 m enclosure, and occasionally to complete one full circuit (7 bats, 10 flights; M. Happold unpubl.). Cursorial locomotion efficient as in *S. dinganii*. In Kruger N. P. in South Africa, roosts by day in hollows in *Colophospermum mopane* trees (Fenton *et al.* 1985; bats identified as *S. viridis* by C. B. Robbins). Most (26 of 29) roosts were in living trees, and the selected trees were on the steep sides and tops of ridges – not in the riverine forests and adjacent mopane woodlands, although hollow mopane trees were present in both places (Fenton & Rautenbach 1986 as *S. borbonicus*). The bats often switched day-roosts, and moved from 100–1000 m between roosts. Radio-tracked individuals of both sexes used 2–6 (mean 4) roosts during 4–10 day observation periods, and did not use a single roost for more than 3–4 days. In Malawi, at 20–21 °C, does not become torpid during the day. Predicted mean maximum urine concentration comparatively low (3233 mOsmol/kg) (Happold & Happold 1988). Captive bats, fed winged termites, drank water every day.

Foraging and Food In Malawi, foraging by slow-hawking was observed in clearings and moderately uncluttered spaces between tree trunks: three light-tagged individuals foraged mainly 2–7 m above ground (M. Happold unpubl.). Foraging flights are characterized by swerving, diving and swooping upwards, and by the absence of acrobatic manoeuvring. In Kruger N. P., individuals moved, while foraging, towards the river and apparently drank before returning to their roosts within an hour (Fenton & Rautenbach 1986). Radio-tracked bats travelled up to 4 km from their roosts. In coastal Kenya in the dry season, the stomach contents of six individuals contained mainly Coleoptera (67% by volume) and Hemiptera (19%), with Orthoptera, Diptera, Homoptera and unidentified insects (14%) (Whitaker & Mumford 1978). In Kruger N. P., analysis of faeces of eight bats during the dry season showed that Coleoptera comprised ca. half of the consumed food, with Diptera, Lepidoptera, Hymenoptera and Hemiptera eaten less often (Fenton *et al.* 1985).

Echolocation In Malawi, calls recorded when seven bats were released, and while three others were tethered, were broad-bandwidth, high-intensity steep FM/QCF sweeps with start-frequencies up to 78 kHz and end-frequencies 37–45 kHz (usually 37–42 kHz) (Figure 118o, p; M. Happold unpubl.). At Mana Pools N. P. in NW Zimbabwe, the calls of two white-bellied bats had end-frequencies of 40.1 ± 0.9 kHz, and those of one yellow-bellied bat had end-frequencies of 37.9 ± 1.0 kHz (mean \pm S.D.; Fenton *et al.* 1998b). The echolocation data suggest that both forms represent *S. viridis*, although Fenton *et al.* (1998b) presumed that the white-bellied and yellow-bellied forms

Scotophilus viridis

represented different species. In Kruger N. P., calls with end-frequency 40 kHz were recorded by Aldridge & Rautenbach (1987, as *S. borbonicus*).

Social and Reproductive Behaviour No information for bats of confirmed identity.

Reproduction and Population Structure Litter-size: 2 ($n = 4$). At 22° 25' S (Pafuri, Kruger N. P., South Africa), where the presence of *S. viridis* has been confirmed from biometrical data, and the presence of *S. leucogaster* is uncertain, the reproductive chronology is restricted seasonal monoestry, with insemination, ovulation and fertilization in autumn (Apr). Early embryonic growth is retarded but not arrested: the embryo remains in the morula stage for 6–8 weeks, followed by a blastocyst stage of ca. two months. Implantation occurs after ca. three weeks. With the onset of warmer weather, embryogenesis accelerates and parturition occurs in Nov (van der Merwe *et al.* 1988, as *S. borbonicus*). At 15–17° S in Malawi, 8 of 8 adult ♀♀ were lactating in Dec, 1 of 1 was post-lactating in Feb and 7 of 7 in Apr–May were neither palpably pregnant nor lactating (M. Happold unpubl.). Volant young with unfused epiphyses were recorded in Oct–Jan. These data suggest seasonal monoestry with births at the end of the dry season and beginning of the wet season (Oct–Nov), but this needs confirmation from year-round observations.

Predators, Parasites and Diseases No information for bats of confirmed identity.

Conservation IUCN Category: Least Concern.

Widespread; probably fairly common; no known threats.

Victor Van Cakenberghe & Meredith Happold

Subfamily MYOTINAE – Wing-gland Bats and Myotis

Myotinae Tate, 1942. Bull. Amer. Mus. Nat. Hist., 80: 229.

Diagnostic combination of characters: second phalanx of third finger ca. as long the first; ears not funnel-shaped; tragus long and narrow but not as sharply pointed as in *Kerivoula* (Figure 116); six upper cheekteeth. Pelage dense, soft and fairly woolly (some species more so than others). Muzzle relatively long. There are three genera, of which two, *Cistugo* and *Myotis*, occur in Africa (but see updated information about *Cistugo* below).

Cistugo (2 species). Wing-glands present but not visible in dried skins (details in species profiles). Profile of forehead region (viewed laterally) moderately concave (see Figure 147 for definition). First two upper premolars greatly reduced and lying transversely to the toothrow (Figure 148).

Myotis (11 species in Africa). Wing-glands absent. Profile of forehead region (viewed laterally) weakly to strongly concave. First two upper premolars reduced but not greatly so, and not lying transversely to the toothrow.

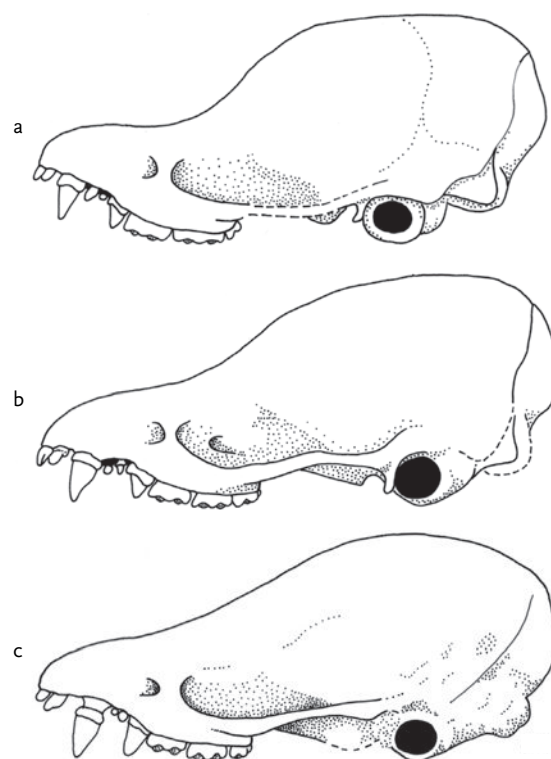

Figure 147. Range of variation in the degree of concavity of the dorsal profile of the forehead region (viewed laterally) in *Cistugo* and *Myotis* occurring in Africa. (a) Strongly concave (e.g. *M. scotti*; holotype, BMNH 27.3.4.1). (b) Moderately concave (e.g. *M. bocagii cupreolus*; BMNH 3.2.4.6). (c) Weakly concave (e.g. *M. dieteri*; holotype, NMHN CG 1985-1925). Cuspidation of inner incisors perhaps inaccurate.

Figure 148. *Cistugo*. Lateral view of skull of *Cistugo lesueuri* (holotype; based on photo by T. Kearney). Occlusal view of upper left teeth showing the anterior and middle premolars lying transversely to the toothrow; in some specimens, the angle of these premolars to the toothrow is sometimes greater and sometimes less than in the illustrated specimen (BMNH 27.4.1.3).

Since the *Myotis* profiles were submitted in 2006, Lack *et al.* (2010) concluded from analysis of mtDNA that *Cistugo* should constitute a distinct family (Cistugidae).

Meredith Happold

GENUS *Cistugo* Wing-gland Bats

Cistugo Thomas, 1912. Ann. Mag. Nat. Hist., ser. 8, 12: 205.

A polytypic genus with two species, both found only in the arid south-west corner of Africa. Diagnostic combination of characters: six upper cheekteeth (as in *Myotis*, *Kerivoula*, *Phoniscus*); ears not funnel-shaped, tragus long and narrow but not sharply pointed and pelage not frizzled (cf. *Kerivoula* and *Phoniscus*); first two upper premolars greatly reduced, and lying more-or-less transversely to the rest of the toothrow between the canine and the posterior (third) premolar; cranium less domed and muzzle less pinched in laterally than in some *Myotis* (including the sympatric species); glands present on the wings (cf. *Myotis*), but the glands are not visible when skins are dried; pelage not copper-red (cf. *Myotis* in southern Africa). Dental formula $2^{133}/_{3133} = 38$. Some craniodental characters of *Cistugo* are shown in Figure 148. For photographs of the wing-glands, see Seamark & Kearney (2006).

Cistugo was considered a subspecies of *Myotis* until Rautenbach *et al.* (1993) discovered that the karyotypes of *C. seabrae* and *C. lesueuri* ($2n = 50$; $aFN = 48$) differed from those of species of *Myotis* from the New and Old Worlds ($2n = 44$; $aFN = 52$). Molecular evidence supports the generic status of *Cistugo* (Bickham *et al.*

2004, Stadelmann *et al.* 2004). Then Lack *et al.* (2010) concluded that *Cistugo* should constitute a distinct family (Cistugidae). Given the similarity of *lesueuri* to *seabrae*, Corbet & Hill (1980) included *lesueuri* in *seabrae*. In contrast, Meester *et al.* (1986) retained *lesueuri* as a separate species but suggested that, in view of their allopatric distribution, *lesueuri* may best be treated as a subspecies of *seabrae*. Simmons (2005) also recognizes both taxa as distinct species. Here, the taxa are provisionally treated as distinct species, but their taxonomic relationship is in need of revision.

The species of *Cistugo* are:

Cistugo lesueuri. Dorsal pelage variable, yellowish-orange, yellowish-brown, pale brown, or reddish-brown; ventral pelage also variable, from medium brown to white. FA: 32–39 mm.

Cistugo seabrae. Dorsal pelage variable, yellowish-brown, orange-brown or greyish-brown; ventral pelage also variable, yellowish-orange, off-white or grey. FA: 33–35 mm.

Teresa Kearney

Cistugo lesueuri LESUEUR'S WING-GLAND BAT

Fr. Cistugine de Lesueur; Ger. Lesueurs Mausohr

Cistugo lesueuri Roberts, 1919. Ann. Transvaal Mus. 6: 112. L'Ormarins, Paarl District, Cape Province, South Africa.

Taxonomy Synonyms: none. The status of *lesueuri* is controversial (see Genus *Cistugo*). Pending further information, *C. lesueuri* is tentatively treated here as a distinct species (following Honacki *et al.* 1982, Simmons 2005). Chromosome number (South Africa): $2n = 50$; $aFN = 48$ (as in *C. seabrae*) (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six

lower cheekteeth on each side (but anterior upper premolar not always visible above gum); ears not funnel-shaped; pelage not frizzled; one or two glands on each wing but not close to forearm (not always present or visible). A very poorly known species, which is almost indistinguishable from *C. seabrae*. Sexes apparently similar. Pelage moderately dense, sleek (not woolly); mid-dorsal hairs ca. 5 mm. Dorsal pelage variable, yellowish-orange, yellowish-brown, pale brown or reddish-brown; hairs dark brown, dark greyish-brown or blackish-brown with tip

of dorsal colour. Ventral pelage colour also variable; individuals with darker dorsal pelage have darker ventral pelage; colour darkest under chin (pale brown or medium brown) becoming paler on neck (cream), and palest in pelvic region; hairs blackish-brown with pale tip or (in pelvic region) white. Muzzle with naked skin brownish-black. Ears blackish-brown, comparatively and relatively short for a vespertilionid (36.1 [28–40]% of FA); tip narrow and rounded. Tragus of medium relative length for a vespertilionid (ca. 54% of E), narrow, bluntly pointed with notch at base of posterior margin. Wings uniformly blackish-brown, possibly with less conspicuous paler reticulation than in *C. seabrae* (but this needs confirmation). The wing-glands are found in various positions on the wing-membrane, but never close to the forearm (cf. *C. seabrae*). Glands comparatively small (cf. *C. seabrae*) and not more than two on each wing. The number of glands per wing varies between wings and between individuals; sometimes absent; not visible on dry skins (Shortridge 1942, Herselman & Norton 1985). Tibiae dorsally and ventrally naked. Interfemoral membrane paler and more translucent than wings and with pale transverse lines in dried specimens (no data for living animals); distal third with fine, thinly scattered, cream hairs (1 mm) along veins on ventral surface only (cf. *C. seabrae*); posterior margin without projecting bristle-like hairs (cf. some *Kerivoula*). Tail 89.0 (78–100)% of HB (cf. *Pipistrellus capensis*). Length of calcar, the presence or absence of a postcalcareal lobe and the projection or otherwise of the terminal vertebrae of the tail, are not known.

Skull (Figure 148) small, delicate. Profile of forehead region (viewed laterally) moderately concave (see Figure 147 for definition). No sagittal crest. Anterior and middle premolars similar in size, both greatly reduced (not reaching cingulum of posterior premolar), crowded with anterior premolar displaced lingually and middle premolar displaced labially to such an extent that both lie more or less transversely across the toothrow (Figure 148) – the degree of transverse displacement is, however, very variable. Anterior upper premolar sometimes not visible above gum. No differences between the skulls and teeth of *C. lesueuri* and *C. seabrae* have been documented.

Geographic Variation None recorded.

Similar Species Three other vespertilionids in southern Africa have three upper premolars on each side and FA <42 mm:

Cistugo seabrae. Slightly paler and on average slightly smaller (FA: 34.4 [33–35] mm; GLS: 12.9 [12.2–13.2] mm). Usually two or three glands per wing; glands larger and usually close to forearm.

Myotis bocagii. Dorsal pelage rufous, dense, fairly woolly. Middle upper premolar ca. half to three-quarters height of anterior premolar; both visible above gum. Forearm on average longer: 38.6 (33–42) mm.

Kerivoula argentata. Ears funnel-shaped, tragus long, narrow, sharply pointed. Fringe of stiff hairs along posterior margin of interfemoral membrane. Dorsal pelage woolly, reddish-brown with silvery-white frosting.

If the anterior upper premolar is not visible, *C. lesueuri* is similar to:

Pipistrellus capensis. Tragus broad and rounded. Transverse lines on interfemoral membrane dark. Tail relatively shorter (65–66% of HB). Premolars not minute.

Distribution Endemic to Africa. Recorded, disjunctly, from the South-West Arid and South-West Cape BZs, and also from the Highveld BZ. The records are from South Africa (Cape and Orange Free State) and Lesotho (Roberts 1919, Herselman & Norton 1985, Lynch & Watson 1990, Lynch 1994, Watson 1998).

Habitat In Lesotho, mist-netted near water (dam, river, vlei) in open montane grassveld in mountainous terrain (Watson 1998). In the Western Cape Province of South Africa, netted over water in fynbos in mountainous terrain (TM).

Abundance Rare.

Remarks Day-roosts include rock-crevices close to water; one was a narrow horizontal crevice in an arid mountain cliff next to a river; another was a rock-crevice behind a waterfall (Lynch 1994, Watson 1998). Insectivorous. Emerges at dusk (Lynch & Watson 1990, Watson 1998). Roosts in mixed-sex groups (several to 40) (Lynch 1994, Watson 1998). Litter-size: 1 (1–2) foetus, n = 18 (Lynch 1994). Reproductive chronology not known; in Lesotho, pregnant ♀♀ were collected in Oct and Dec; no data for other months (Lynch 1994). Predators and ectoparasites not known. The possibility that this species is a reservoir host of Rift Valley Fever virus is indicated by Oelofsen & Van der Ryst (1999).

Conservation IUCN Classification: Least Concern.

However, surveys suggest that this species has a very small population.

Cistugo seabrae ANGOLAN WING-GLAND BAT

Fr. Cistugine d'Angola; Ger. Angola-Mausohr

Cistugo seabrae Thomas, 1912. Ann. Mag. Nat. Hist., ser. 8, 10: 205. Mossamedes, Angola.

Taxonomy Synonyms: none. Tentatively not considered to include *lesueuri* (but see Genus *Cistugo* and *C. lesueuri*). The specific name is commonly spelled *seabrai* but *seabrae* is the original spelling. Chromosome number (Namibia): 2n = 50; aFN = 48 (as in *C. lesueuri*) (Rautenbach *et al.* 1993).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side (but anterior upper premolar not always visible above gum); ears not funnel-shaped; pelage not frizzled; usually 2–3 glands close to forearm on each wing (but not always present or visible). A poorly known species almost indistinguishable from *C. lesueuri*. Sexes similar. Pelage moderately dense, sleek (not woolly); mid-dorsal hairs ca. 5 mm. Dorsal pelage yellowish-brown, orange-brown or greyish-brown; hairs medium to dark brown with tip of dorsal colour. Ventral pelage yellowish-orange (when dorsal pelage is orange-brown), off-white or beige; paler in pelvic region; hairs greyish-brown or blackish-brown with tip of ventral colour or (in pelvic region) white with grey base. Muzzle with naked skin dark brown. Ears medium brown, comparatively and relatively short for a vespertilionid (27.9 [25–37]% of FA); tip narrow, rounded. Tragus length not known. Wings medium to dark brown with paler reticulation lines (at least in dried specimens). Glands on wing usually found close to forearm; larger than in *C. lesueuri* and usually two or three on each wing (Thomas 1912a, Hill & Carter 1941, Shortridge 1942, Herselman & Norton 1985). Tibiae dorsally and ventrally naked. Interfemoral membrane paler and more translucent than wings and with pale transverse lines; distal third with fine, thinly scattered cream hairs along veins ventrally and dorsally (cf. *C. lesueuri*); posterior margin without projecting bristle-like hairs (cf. some *Kerivoula*). Tail 82.1 (71–91)% of HB (cf. *Pipistrellus capensis*). Calcar reaching half-way to tip of tail. No postcalcareal lobe. Not known if terminal vertebra protrudes beyond margin of interfemoral membrane.

No differences between the skulls and teeth of *C. lesueuri* and *C. seabrae* have been documented.

Geographic Variation None recorded for *C. seabrae* as defined here, but Meester *et al.* (1986) suggest that *C. lesueuri* might be a subspecies of *C. seabrae*.

Similar Species Three other vespertilionids in southern Africa have three upper premolars on each side and FA <42 mm:

Cistugo seabrae

Cistugo lesueuri. Slightly darker and on average slightly smaller (FA: 35.6 [32–38] mm, GLS: 13.3 [12.9–13.8] mm). No more than two glands per wing; glands smaller and not found near forearm.

Myotis bocagii. Dorsal pelage rufous, dense, fairly woolly. Middle upper premolar ca. half to three-quarters height of anterior premolar; both visible above gum. FA on average longer (38.6 [33–42] mm).

Kerivoula argentata. Ears funnel-shaped, tragus long, narrow, sharply pointed. Fringe of stiff hairs along posterior margin of interfemoral membrane. Dorsal pelage woolly, reddish-brown with silvery-white frosting.

If the anterior upper premolar is not visible, *C. seabrae* is similar to:

Pipistrellus capensis. Tragus broad and rounded. Transverse lines on interfemoral membrane dark. Tail relatively shorter (65–66% of HB). Premolars not minute.

Distribution Endemic to Africa. Apparently restricted to the Namib Desert region of the South-West Arid BZ. Recorded from SW Angola (Mossamedes), Namibia (Berseba, Huab River Mouth, Lüderitz District, 70 km W Maltahohe) and NW South Africa (Goegab, Steyerskraal, Goodhouse) (Thomas 1912a, Shortridge 1934, 1942, Herselman & Norton 1985). A new record (not mapped) on the Orange R. at 28° 39' S, 20° 26' E, extends the range eastwards by 216 km (Seamark & Kearney 2006).

Habitat Found in arid areas, in the vicinity of open water (Shortridge 1942, Herselman & Norton 1985).

Abundance Rare in collections, but plentiful at some localities where collected (Shortridge 1942, Herselman & Norton 1985).

Remarks Day-roosts not known – all specimens have been netted or shot. However, individuals found flying in a church were thought to have been roosting in the spire (Shortridge 1934). Insectivorous. Observed foraging a few metres off the ground, over vegetation and over or near water, shortly after sundown (Shortridge 1942, Herselman & Norton 1985). Shortridge (1942) observed that, on first appearing, its flight is comparatively steady and direct but, with approaching dusk, it descends and circles low around trees and bushes. At Goodhouse, *Cistugo* and *Sauromys* (as *Platymops*) have the same habit of fluttering in the deep shadow of orange trees and snapping small insects from the leaves.

Conservation IUCN Classification: Least Concern.

Populations small but not under any specific threat at present.

GENUS *Myotis*

Myotises (Mouse-eared Bats, Hairy Bats)

Myotis Kaup, 1829. Skizz. Entwickel.-Gesch. Nat. Syst. Europ. Thierwelt 1: 106. Type species: *Vespertilio myotis* Borkhausen, 1797.

Myotis welwitschii.

A polytypic genus with 104 species of which only ca. 20% occur in the southern hemisphere, and only 11 species occur in Africa. Diagnostic combination of characters: six upper cheekteeth (as in *Cistugo*, *Kerivoula*, *Phoniscus*) but sometimes the middle premolar is not visible from the outside lateral view although it is visible in the occlusal view; ears not funnel-shaped, tragus long and narrow

but not sharply pointed and pelage not frizzled (cf. *Kerivoula* and *Phoniscus*); anterior upper premolar and middle premolar not aligned transversely to the toothrow and no glands on the wings (cf. *Cistugo*). Pelage thick, soft, erect, often fairly woolly. Dental formula $2^{133}/_{3133} = 38$. Selected external characters of *Myotis* occurring in Africa are illustrated in Figure 149, and craniodental characters in Figure 150.

This genus is widely distributed over Africa, Eurasia and south-eastwards to Australia, and the Americas, but is sparsely distributed on oceanic islands. It has the widest distribution of any genus of bats and probably the widest natural distribution of any terrestrial mammal except *Homo* (Nowak 1999). Among mammals, the genus *Myotis* has had one of the most extensive adaptive radiations and, because the genus is so widespread, it appears that separate radiations have taken place in different localities with the result that convergent evolution has also occurred (see below). In Africa, there are 11 species and, of these, five occur in North Africa, mainly in the Mediterranean Coastal BZ but sometimes also in the Afromontane–Afroalpine BZ and in one case, also marginally in the Sahara Arid BZ. The remaining six species are sub-Saharan and, of these, two are known only from forest habitats, one only from savanna habitats and three occur in both. Altogether, eight of the species in Africa have been found in montane habitats; *M. scotti* is the only species that might be restricted to montane habitat, but most records of *M. welwitschii* are near mountainous regions although not restricted to high altitudes.

Figure 149. Some external characters of African *Myotis*. Ventral views of interfemoral membranes, tibiae, hindfeet and calcars of (a) *M. capaccinii*, (b) *M. nattereri* and (c) *M. mystacinus*; tibiae drawn to same size to show differences in sizes of hindfeet relative to lengths of tibiae; traced from photos of dried specimens. (d) Left ear and tragus of *M. bocagii*. (e) Left ear and tragus of *M. emarginatus* (based on Harrison & Bates 1991). Particoloured flight membranes of (f) *M. welwitschii*, (g) *M. morrisi* and (h) some specimens of *M. tricolor*.

The foraging strategies exemplified by *Myotis* are diverse and include slow-hawking, trawling, gleaning from foliage and walls, and perhaps ground-gleaning. The echolocation calls emitted by bats cruising in their main habitats are unlike those of other African vespertilionids; they are mainly very steep linear FM sweeps, which apparently have very

variable end-frequencies as well as variable start-frequencies. However, Barataud (2005) analysed the echolocation of seven species of *Myotis* (including four of those occurring in North Africa) and found that they emit several types of signals (up to six different types for one species) according to their flight behaviour and their distance from obstacles.

Some slow-hawking species of *Myotis* use the interfemoral membrane to catch and/or hold prey, and others use their hindfeet as grappling hooks to catch (gaff) prey on or near the surface of water in pools, lakes, streams and rivers. It was formerly thought that the suites of characters that reflect adaptation to the different foraging strategies were characteristic of the subgenera – namely, *Myotis* (gleaning off solid surfaces), *Selysius* (slow-hawking over land) and *Leuconoe* (trawling or slow-hawking over water) (e.g. Koopman 1994). However, it is now evident (from molecular systematics) that these subgenera are not monophyletic but instead represent ecomorphs whose distinguishing characters reflect convergent evolution (Ruedi & Mayer 2001, Stadelmann *et al.* 2004). Consequently, these subgenera are not recognized by Simmons (2005) or here.

The molecular evidence of Stadelmann *et al.* (2004) indicates the existence of an Ethiopian clade of *Myotis*, which includes the six sub-Saharan species, one species from Madagascar, one species from the Western Palearctic (*M. emarginatus*) and one from the Oriental region (*M. formosus*). The data suggest that the Ethiopian clade split from the other Old World *Myotis* in the middle Miocene, quite early in the *Myotis* radiation and therefore the comparative paucity of species in sub-Saharan Africa cannot be attributed to a late entry into this continent. The data also suggest that the Western Palearctic and Oriental regions were colonized secondarily from the Ethiopian region, probably at the end of the Miocene.

Because different foraging strategies are associated with different morphological characters, many of the diagnostic characters of the species in this genus reflect the manner in which they capture prey. These characters include the relative length of the tragus, the hairiness or otherwise of the tibiae; the relative length of the hindfeet, the

relative length, robustness and hairiness of the calcars and the development of postcalcarea lobes; the position of attachment of the wing to the hindlimb (i.e. attached to base [distal end] of tibia or to base [proximal end] of first toe), and the pilosity of the posterior margin of the interfemoral membrane (Figure 149; details below) (Fenton & Bogdanowicz 2002). Other diagnostic characters include the colour of the pelage and wings, the relative length and shape of the ears, and the presence or absence of a deep emargination in the outer margin of the ear (Figure 149). Diagnostic characters of the skull and dentition include skull size and robustness, the comparative height of the braincase and degree of concavity of the profile of the forehead region (viewed laterally), which ranges, in African *Myotis* and *Cistugo*, from strongly to weakly concave (Figure 147), and the relative size of the middle upper premolar (P^3) and its position in the toothrow.

The relative sizes of some characters, for African species, are as follows:

Mean length of ear as percentage of mean length of FA. For African *Myotis*, 27.0–34.7% is short, 34.8–38.3% is medium, 38.4–42.0% is long.

| Distribution in Africa | FA (mm) | Wings and interfemoral membrane | Relative length of hindfoot (Wing attachment) | Dorsal hairs (Dorsal pelage) | Ventral hairs | |
|--|---------|---|---|---|---------------|--|
| North-west Africa | 53–65 | Uniformly brown | Medium (Base of first toe) | Bicoloured (Medium to pale brown) | Bicoloured | |
| North-west Africa | 39–43 | Uniformly greyish-brown | Long (Tibia, well above heel) | Bicoloured (Pale brownish-grey) | Bicoloured | |
| North-west Africa | 39–43 | Uniformly greyish-brown | Short (Base of first toe) | Tricoloured (Greyish-brown to rusty-brown) | Bicoloured | |
| North-west Africa | 37–42 | Uniformly dark greyish-brown | Medium (Base of first toe) | Bicoloured (Greyish-brown) | Bicoloured | |
| North-west Africa | 33–37 | Uniformly dark brown | Short (Base of first toe) | Bicoloured (Greyish-brown) | Bicoloured | |
| Ethiopia to South Africa, and westwards to Angola. Also Guinea, Cameroon | 52–60 | Conspicuously parti-coloured, black and orange | Short (Base of first toe) | Tricoloured (Orange) | Bicoloured | |
| Ethiopia to South Africa | 47–53 | Uniformly dark or inconspicuously particoloured, black and dark red | Medium (Base of first toe) | Tricoloured (Rufous to coppery-brown) | Tricoloured | |
| Nigeria, Ethiopia | 45, 47 | Particoloured, black and yellowish | Short (Base of first toe) | Tricoloured (Orange-brown) | Unicoloured | |
| Congo | 37 | Uniformly blackish | Long (Base of tibia) | Bicoloured ('Pale auburn') | Bicoloured | |
| West Africa to Tanzania and southwards to Angola and NE South Africa | 33–42 | Uniformly blackish-brown | Medium (Base of first toe) | Bicoloured or tricoloured (Rufous, coppery-red or dark rusty-brown) | Bicoloured | |
| Ethiopia | 37–41 | Uniformly dark brown | Short (Base of first toe) | Bicoloured (Coppery-brown) | Bicoloured | |

| | Profile of forehead region | Miscellaneous | Species |
|--|--------------------------------|---|-----------------------|
| | Moderately concave | No fringe of bristle-like hairs along posterior edge of interfemoral membrane | <i>M. punicus</i> |
| | Strongly concave | Outer margin of ear slightly notched
Tragus ca. half length of ear
No fringe of bristle-like hairs along margin of interfemoral membrane | <i>M. capaccinii</i> |
| | Strongly concave | Outer margin of ear deeply notched
Tragus ca. half length of ear
No fringe of bristle-like hairs along margin of interfemoral membrane | <i>M. emarginatus</i> |
| | Strongly concave | Outer margin of ear slightly notched
Tragus notably > half length of ear
Dense fringe of bristle-like hairs along margin of interfemoral membrane | <i>M. nattereri</i> |
| | Strongly concave | Outer margin of ear with shallow notch
Tragus ca. half length of ear
No fringe of bristle-like hairs along margin of interfemoral membrane | <i>M. mystacinus</i> |
| | Moderately concave | Sparse fringe of bristle-like hairs along margin of interfemoral membrane between tips of calcars and tip of tail | <i>M. welwitschii</i> |
| | Strongly concave | No fringe of bristle-like hairs | <i>M. tricolor</i> |
| | Strongly concave | No fringe of bristle-like hairs along margin of interfemoral membrane | <i>M. morrisi</i> |
| | Weakly concave | Scattered short hairs along proximal two-thirds of margin of interfemoral membrane | <i>M. dieteri</i> |
| | Moderately to strongly concave | No fringe of hairs along margin of interfemoral membrane | <i>M. bocagii</i> |
| | Strongly concave | Numerous stiff hairs along margin of interfemoral membrane between tips of calcars and tip of tail | <i>M. scotti</i> |

Table 29. Key to the African species in the genus *Myotis*. Measurements and distributions pertain only to Africa.

Mean length of tragus relative to length of ear. About one-third of E is short, ca. half of E is medium, ca. two-thirds of E is long.

Mean length of hindfoot as percentage of mean length of tibia. For African *Myotis*, 36–49% is short, 49–62% is medium, 62–74% is long.

Relative length of calcar. Reaching ca. one-third of distance to tip of tail is short, ca. half of distance is medium, ca. two-thirds of distance is long.

Relative height of middle upper premolar. About same height as cingulum of anterior premolar is small, ca. half height of anterior premolar is medium, ca. two-thirds height of anterior premolar is large.

The species occurring in Africa can be distinguished from the information in Table 29. Additional diagnostic characters are given in the species profiles.

Meredith Happold

Myotis bocagii RUFOUS MYOTIS (RUFOUS MOUSE-EARED BAT)

Fr. Murin roux; Ger. Kupferfarbenes Mausohr

Myotis bocagii (Peters, 1870). J. Sci. Math. Phys. Nat. Lisboa, ser. 1, 3: 125. Duque de Bragança, Angola.

Taxonomy Originally *Vespertilio bocagii*. Because the species was named after J. V. Barboza du Bocage, some authors spell the name *bocagei*. Synonyms: *cupreolus*, *dogalensis*, *hildegardae*. Three subspecies: two in Africa. Chromosome number (South Africa): $2n = 44$; aFN = 50 (Rautenbach *et al.* 1993).

Description Small to very small, very beautiful microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears separated, not funnel-shaped; pelage not frizzled; FA: 33–42 mm; dorsal pelage rufous, coppery-red or dark rusty-brown; face sometimes with dark mask; wings uniformly blackish-brown, attaching to base of first toe; HF 47–60% of Tib; posterior margin of interfemoral membrane naked. Not easily distinguished from *M. scotti*. Sexes similar in colour and size. Pelage dense, fairly woolly; mid-dorsal hairs 5–6 mm. Dorsal pelage pale to bright rufous, bright coppery-red to dark rusty-brown; hairs vary geographically – tricoloured (cream with dark brown bases and rufous tip), or bicoloured (dark reddish-brown with rufous, coppery-red or dark rusty-brown tip). Ventral pelage cream or pale silvery-brown sometimes suffused with rufous; hairs bicoloured, blackish-brown with tip of ventral colour. Muzzle and naked skin around eyes dark brown. In some specimens of *M. b. bocagii*, pelage on cheeks and around eyes is also blackish or brown, creating a dark ‘mask’ across the face (similar to, but not as conspicuous as, that of *M. scotti*). Ears blackish-brown; of medium relative length for an African *Myotis* (37.1 [32–43]% of FA, $n = 31$); inner margin strongly convex, outer margin concave with no emargination. Tragus relatively short (43 [39–45]% of E). Wings uniformly dark blackish-brown without markings; attaching to base (proximal end) of first toe. Tibia hairless. Hindfoot of medium relative length (53 [47–60]% of Tib, $n = 23$). Calcar moderately robust, extending half to two-thirds of distance to tip of tail. Postcalcarea lobe poorly developed. Interfemoral membrane dark blackish-brown; posterior margin without fringe of hairs (cf. *M. scotti*). Tail with two vertebrae protruding beyond edge of interfemoral membrane.

Skull small and delicate. Braincase comparatively low; profile of forehead region (viewed laterally) moderately (Figure 147b) to strongly concave. No sagittal crest. Anterior palatal emargination comparatively wide (cf. *M. morrisi*) (Figure 150d). Upper canines (from top of cingula) 1.63 (1.5–1.8) mm, $n = 7$ (cf. *M. scotti*). Middle upper premolar comparatively large (half to three-quarters height of anterior upper premolar and much more than half crown area of anterior premolar);

usually displaced lingually but anterior and posterior premolars well separated (Figure 150f). Anterior upper premolar also somewhat displaced lingually. Anterior and middle lower incisors with four cusps.

Geographic Variation Following Koopman (1994) the African subspecies are:

Myotis b. bocagii: Ethiopia to Angola and the former Transvaal; woodland savanna. Dorsal pelage rufous, hairs tricoloured. Sometimes with dark mask.

M. b. cupreolus: Liberia to DR Congo; rainforest. Dorsal pelage coppery-red to dark rusty-brown (usually darker than nominate subspecies), hairs usually bicoloured. Some individuals in DR Congo are pale rufous. No mask.

Similar Species Four other sub-Saharan *Myotis* have uniformly coloured wings (Table 29, p. 691):

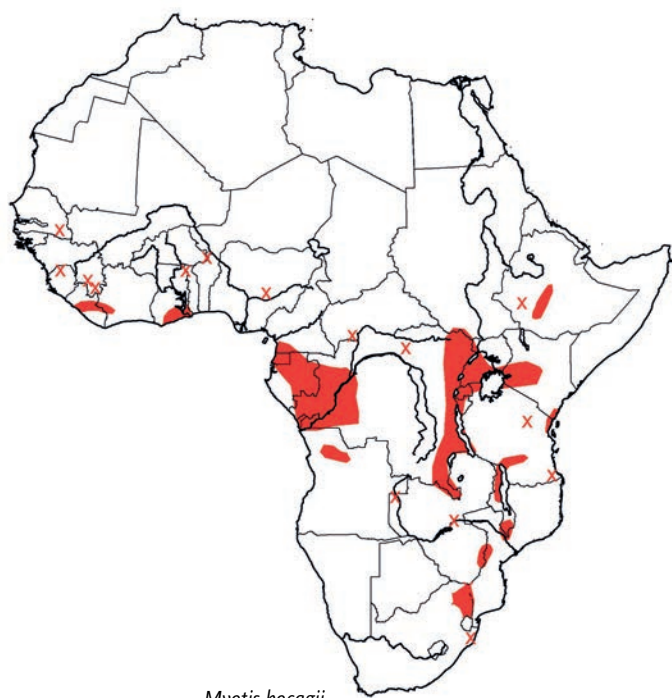

Myotis scotti. Dorsal pelage bicoloured. Posterior margin of interfemoral membrane with bristle-like hairs between ends of calcars and tip of tail. HF <50% of Tib. Braincase comparatively high; profile of forehead strongly concave. Upper canines shorter (ca. 1.2 mm). Middle upper premolar smaller (ca. half height of anterior premolar or less); within toothrow.

M. dieteri. Dorsal hairs dark brown with auburn tip. HF 65% of Tib. Skull with profile of forehead region weakly concave.

M. tricolor (sometimes). Larger (FA: 47–52 mm). Wings sometimes with faint black and dark reddish-brown pattern.

Distribution Widely distributed and recorded in Sudan Savanna BZ and most other biotic zones and mosaics south of the Sudan Savanna BZ, but not recorded from the Horn of Africa, nor from the South-West Arid, Highveld and South-West Cape BZs. Recorded from most countries from Senegal to N DR Congo, Uganda, Kenya and Ethiopia, and southwards to Angola and NE South Africa. According to Monadjem *et al.* (2010) more widely distributed in eastern half of Zimbabwe than mapped here, and also recorded further south in KwaZulu–Natal. Extraliminally: Yemen.

Habitat Recorded from riverine habitats in lowland rainforest and woodland savannas in West Africa, coastal forests in East Africa, and

Myotis bocagii

miombo woodland in the south. In savanna zones, probably limited to localities within or near remnant rainforest, riverine forest or afromontane forest, which are also within reach of open water such as rivers, large pools, dams and lakes. Often recorded where bananas are grown and sometimes apparently absent where musaceous plants are absent (see Adaptations). Appears to avoid villages.

Abundance Uncertain. Not often encountered and considered uncommon throughout most of its geographic range, but common in some localities where forest, banana plants and open water are present (Brosset 1976, Happold & Happold 1997).

Adaptations Aspect ratio low; wing-loading very low (M. Happold unpubl.). Flight fast or slow with great manoeuvrability; can take off from ground; cannot hover. Turns usually by banking (minimum radius <25 cm), occasionally by stalling-and-twisting; individuals sustained flight within a 1×1×1 m enclosure for up to four circuits/flight (6 bats, 10 flights each). Cursorial locomotion is slow and awkward. By day, roosts in the furled leaves of bananas and other musaceous plants; in bunches of bananas and under the dead leaves of bananas and plantains (Lang & Chapin 1917b). In DR Congo, the Mabudu people call it 'big red brother' of the Banana Pipistrelle *Pipistrellus nanus*. In Gabon, *M. bocagii* roosted 5–50 m from the Ivindo R. and was not found in rainforest along the river where there were no banana plants (Brosset 1976). Has also been found clinging to broad leaves in dank, dark vegetation of a thickly overgrown swamp and one pair, when disturbed, flew from the sheath of an Arum lily into the sheath of another lily some distance away (Sanborn 1949). Also roosts among leaves of *Hyphaene* palms (Rosevear 1965) and in hollow trees (R. C. Wood, in Kershaw 1922).

Foraging and Food Forages mainly by trawling and slow-hawking over water, taking prey from the surface and, less often, from above the surface. One light-tagged individual in Malawi foraged over a large

Figure 151. Sonogram of a sequence of search-phase and approach-phase echolocation calls emitted by a light-tagged *Myotis bocagii* while foraging low over a large farm dam and then approaching prey close to, or on, the surface of the water (M. Happold unpubl.).

farm dam for more than 1.5 hours with only one four-minute break after 55 minutes. This bat, and others, flew long straight or gently curving sweeps with occasional zig-zagging (usually within ca. 20 cm of the surface), with 5–6 dips/min to take prey from the surface, and occasional upward swoops in pursuit of insects flying 1–2 m (sometimes up to ca. 6 m) above the water. Most foraging was done more than 10 m from the edges (M. Happold unpubl.). Brosset (1966) suggests that prey on water surfaces, or just below, is gaffed by the hindfeet. Feeds on minute insects including moths, beetles, Diptera and Orthoptera (Lang & Chapin 1917b, Whitaker & Mumford 1978).

Echolocation Search-phase echolocation calls are very steep linear FM sweeps (Figures 118q and 151). Start-frequency 52–70 kHz; end-frequency 30–33 kHz; peak-frequency 34–35 kHz; band-width 26–40 kHz; call-duration ca. 3.5–5.5 ms (1 bat, light-tagged, foraging over open water; 78 calls; M. Happold unpubl.).

Social and Reproductive Behaviour The social organization of a marked population was studied over a period of 38 months at Makokou in NE Gabon (Brosset 1976). The bats roosted in furled banana leaves in plantations along the Ivindo R., over which they foraged at night. Banana leaves open after a few days and the bats must move into a new leaf, but clumps of bananas produce new leaves often enough to allow leaf-roosting bats to show roost-fidelity to particular clumps. The social organization of these bats is based on resource-defence polygyny. The bats lived in harems comprised of one adult ♂ and 2–7 adult ♀♀ and their young, the entire group roosting together in one furled leaf. Adult ♂♂ without harems roosted singly; sometimes near the roosts of harems, and sometimes at some distance away. In the main study area, there were four harems. Each occupied a distinct clump of bananas, and the distance between harems was 600–1000 m. Group-composition was stable with respect to the ♀♀, but turnover of the ♂♂ was quite rapid. Juveniles disappeared from the parental harem when 4–5 months old. Of nine juvenile ♂♂ marked in their parental harems, two returned when a year old and became 'harem-masters'. One took over a harem near his parental harem; the other took over his parental harem. Harem formation is often associated with adult ♀♀ outnumbering adult ♂♂. During this study, 61 adult ♀♀ were captured, but only 26 adult ♂♂, although the sex ratio at birth was balanced, suggesting that mortality is higher in ♂♂ than in ♀♀. Harem mating systems evolve when it is feasible for one ♂ to defend

a group of ♀♀ directly, or to defend some limited resource used by more than one ♀. In this case, roosts are not in short supply, but prime feeding territories over stretches of the river near roosting sites are perhaps limited and worth defending. Adult ♀♀ (whose roost-fidelity extends far beyond the tenure of the harem ♂♂) are probably attracted by the territory and/or the roost, rather than by a particular ♂. However, ♂♂ that can defend a roost occupied by ♀♀, presumably have unimpeded access to those ♀♀ when they are ready for mating.

Reproduction and Population Structure Litter-size: one (n = 10) or 2 (n = 1). At 00°40'N (Makokou, Gabon), the reproductive chronology is polyoestry with births in Dec–Feb and Jun. These are the two drier seasons when insects become concentrated in the vicinity of rivers and marshes, and provide optimal foraging for these bats. Evidence of polyoestry comes from a marked ♀ who gave birth in Jan and was heavily pregnant the following Jun, and three other marked ♀♀ who gave birth three times within two years (Brosset 1966, 1976). The extent to which ♀♀ are in reproductive synchrony is not known. There is other evidence of births in ca. Jan and ca. Jun in equatorial rainforest habitats: at 2–3°N in NE DR Congo, a heavily pregnant ♀ was recorded in early Jan and a birth in Jun (Lang & Chapin 1917b) and in Equatorial Guinea, a late pregnancy was recorded in early Jan and a young bat in late Jun (Jones 1971). At 15–16°S in Malawi, 1 of 3 adult ♀♀ was palpably pregnant (early) and two were not palpably pregnant in Sep, 1 of 1 was pregnant in Oct, 2 of 5 were pregnant, one was lactating, one was post-lactating and one was reproductively inactive in Jan, 1 of 1 was post-lactating in Feb, 2 of 8 were post-lactating and six reproductively inactive in Mar, and 6 of 6 were parous but reproductively inactive in May. This suggests that polyoestry at this latitude is unlikely unless two births occur within the Nov–Mar wet season.

Predators, Parasites and Diseases Ectoparasites include a flea *Lagaropsylla consularis* (Siphonaptera: Ischnopsyllidae); mites *Spinturnix walkeri* (Acari: Spinturnicidae), *Steatonyssus javensis* (Acari: Macronyssidae) (Dusbábek & Bergmans 1980, Anciaux de Faveaux 1984). Also mites *Psorergatoides kerivoulae* (Acari: Leeuwenhoeekiidae), *Alabidocarpus eptesicus*, *Olalidocarpus myoticola* and *O. squamosus* (Acari: Chirodiscidae), the hosts of these mites were erroneously identified as *Kerivoula smithii* by their describer, A. Fain (J. Fahr pers. comm.).

Conservation IUCN Category: Least Concern.

Widespread; no known threats.

Myotis capaccinii LONG-FINGERED MYOTIS

Fr. Murin de Capaccini; Ger. Langfußfledermaus

Myotis capaccinii (Bonaparte, 1837). Fauna Ital. 1, fasc. 20. Sicily, Italy.

Taxonomy Originally *Vespertilio capaccinii*. Synonyms: six (none in Africa). Subspecies: none recognized by Simmons (2005). Chromosome number (Spain): 2n = 44; aFN = 52 (Pérez-Suárez *et al.* 1991). In Italy, 2n = 44; aFN = 50 (Capanna *et al.* 1968).

Description Small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 39–43 mm; dorsal hairs bicoloured; wings uniformly greyish-brown, attaching to tibia well above heel, HF 70–83% of Tib (cf. all other *Myotis* in North Africa); posterior margin of interfemoral membrane without fringe of bristle-like hairs (Figure 149a). Females on average slightly larger than ♂♂. Pelage soft, dense, silky; mid-dorsal hairs 6–7 mm. Dorsal pelage pale brownish-grey; hairs bicoloured, basal half dark blackish-brown, terminal half pale brownish-grey. Ventral pelage white to yellowish, sharply delineated from dorsal pelage especially between ear and shoulder; hairs bicoloured, blackish-brown with white to yellowish

tip. Juveniles dorsally darker and more brown than adults. Muzzle naked from prominent nostrils to eyes, rufous-brown to dark grey. Ears greyish-brown; relatively short for an African *Myotis* (27–37% of FA, n = 9); outer margin with slight notch. Tragus S-shaped with bluntly pointed tip; only ca. half of E. Wings uniformly greyish-brown without markings; attaching to distal end of tibia clearly above heel (Figure 149a) (cf. attaching to base of first toe in other North African species of *Myotis*). Tibiae hairy, especially on outer edge. Hindfeet relatively large (70–83% of tibia, n = 11); toes with long hairs and long claws. Calcars straight, extending ca. one-third of distance to tip of tail, and each with ‘false end’ two-thirds to three-quarters of the way down its length. Postcalcareal lobe poorly developed or absent. Interfemoral membrane greyish-brown, thickly covered by brown downy hairs especially near the body; posterior margin without any curved, bristle-like hairs (although soft, straight hairs project beyond the proximal half of the margin where membrane is supported by the calcars). Terminal vertebra protruding beyond interfemoral membrane (but not in all specimens).

Skull small and delicate. Braincase comparatively high, profile of forehead region (viewed laterally) strongly concave. No sagittal crest. Middle upper premolar slightly reduced (rising over half height of anterior premolar and ca. half of its crown area); within tooththrow.

Geographic Variation None recorded in Africa.

Similar Species Three other *Myotis* with FA <45 mm occur in NW Africa:

Myotis emarginatus. Dorsal pelage greyish-brown to rufous-brown, woolly; hairs tricoloured. Hindfoot almost always smaller (9–12 mm; 43–54% of Tib). Wing-membrane attaching to base of first toe. Interfemoral membrane naked. Outer edge of tibia not hairy. Notch in posterior margin of ear deep.

M. mystacinus. FA shorter (33–37 mm). Dorsal pelage dark greyish-brown. Hindfoot smaller (7–8 mm; 40–52% of Tib). Wing-membrane attaching to base of first toe. Interfemoral membrane naked.

M. nattereri. Dorsal pelage greyish-brown. Hindfoot smaller (8–10 mm; 46–60% of Tib). Wing-membrane attaching to base of first toe. Interfemoral membrane naked. Tragus longer (ca. 11–12 mm); notably more than half of E.

Distribution In Africa, only recorded from coastal fringe of the Mediterranean Coastal BZ in the northern Maghreb (N Morocco to N Tunisia) (Vaughan *et al.* 1977, Aulagnier & Thévenot 1986, Kowalski & Rzebik-Kowalska 1991). Extraliminally: found in the Mediterranean zone and islands of Europe and Asia Minor, extending east to Iran and Uzbekistan.

Habitat Recorded in the vicinity of rivers, mountain streams, ponds and lagoons, and often in the vicinity of caves, from the coast to mountainous areas. Mainly recorded from sea level to 600 m. At

Aokas in Algeria, some individuals roosted in a cave opening close to the sea and only slightly above its level; the cave is surrounded by mountain slopes overgrown with short Mediterranean shrubs (garrigue) (Kowalski *et al.* 1986).

Abundance Very scarce in NW Africa. Few specimens have been observed or mist-netted; only two locality records in Morocco, four in Algeria and one in Tunisia. None found during recent surveys of roosts in Morocco. Extraliminally, many colonies have disappeared in Spain and France, but the species is locally abundant in the eastern Mediterranean (with a colony of 10,000 ♀♀ in Albania [Chytil & Vlasin 1994]).

Adaptations Aspect ratio not known; wing-loading low (Norberg & Rayner 1987). Roosts by day in caves, mines and crevices that are not far from water; one Moroccan specimen roosted in a hole in a tree. Mainly in summer, often shares caves, and even clusters, with other bats, including *Miniopterus schreibersii*, *Myotis punicus*, *Rhinolophus ferrumequinum* and *R. euryale* (Laurent 1944, Brosset 1958, Vaughan *et al.* 1977). Hibernates during winter (Dec–Feb).

Foraging and Food Forages mainly by trawling and slow-hawking – using its large feet and/or interfemoral membrane to take small to medium-sized insects from the surface of water or flying just above the surface (Kalko 1990). Forages over mountain streams, rivers and ponds and even lagoons (where most Algerian specimens have been mist-netted). In S France, feeds mainly on Trichoptera and Diptera (Chironomidae and Culicidae) (Médard & Guibert 1993), and occasionally takes small fish (Aihartza *et al.* 2003).

Echolocation Highly variable depending on activity and habitat; these data refer to cruising calls in the main habitat. Search-phase call-shape (while hunting above water surface) hyperbolic FM. Start-frequency 43 kHz; end-frequency 22 kHz; peak-frequency 28–35 kHz; call-duration 6–9 ms, inter-call interval 145–165 ms (Barataud 2002, 2005).

Social and Reproductive Behaviour Mating takes place in the winter-roosts where this species gathers in small colonies (western part of the geographic range). Groups of up to 12 recorded in Algeria (Kowalski & Rzebik-Kowalska 1991). Sexes segregate from Mar to Jun when they migrate to summer-roosts. Some individuals roost singly. Pregnant ♀♀ establish maternity colonies in warm caves; they huddle together in dense clusters on the ceilings.

Reproduction and Population Structure Litter-size (Algeria): one ($n = 3$) (Brosset 1958, Kowalski & Rzebik-Kowalska 1991); extraliminally, usually one. In Europe, the reproductive chronology is restricted seasonal monoestry with births in mid- to late Jun. Young are volant after 3–4 weeks. In N Algeria, a pregnant ♀ was reported in early May, and a lactating ♀ in early Jun (Kowalski *et al.* 1986). In N Morocco, large young were observed in late May (Brosset 1958), indicating births in late Apr to early May.

Predators, Parasites and Diseases Predators poorly documented with only one report of predation in a hibernating group by an unidentified animal. Ectoparasites in Africa not known (Anciaux de Faveaux 1984).

Myotis capaccinii

Conservation IUCN Category: Vulnerable (based on African and extralimital data).

This species has specific habitat requirements and its remnant populations are threatened by the draining and polluting of waters over which it forages and by human disturbance in its scarce cave roosts.

Myotis dieteri DIETER'S MYOTIS

Fr. Murin de Dieter; Ger. Dieters Mausohr

Myotis dieteri M. Happold, 2005. Acta Chiropterologica 7: 11. Grotte du Viaduc à Loudima, Congo (04° 15' S, 13° 00' E).

Taxonomy Synonyms: *megalopus* (not of Dobson, 1875). The holotype (only known specimen) was identified as *Myotis megalopus* (Dobson, 1875) by Aellen & Brosset (1968) who first reported the specimen, and by Adam & Le Pont (1974) who gave information relating to its capture in Congo by J.-P. Adam. Adam's specimen was identified as *M. megalopus* because some of its external characters (including long hindfeet) fitted the type description of *M. megalopus* originally thought to have come from nearby in Gabon. Subsequently, the holotype and one other specimen of *M. megalopus* were indicated to have come from Kashmir (Blanford 1888, 1891), and then Thomas (1915c) indicated that *megalopus* is a synonym of *M. longipes* (Dobson, 1873) from Kashmir and thereabouts. This conclusion is upheld by several authors, including Simmons (2005). Hayman & Hill (1971), Dowsett *et al.* (1991) and Grubb (2004) noted that Adam's specimen indicated that a long-footed *Myotis* occurred in Congo and that its identity needed investigation. It was found to represent a new species (Happold 2005). Subspecies: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears separated, not funnel-shaped; pelage not frizzled; FA: 37 mm; dorsal pelage brown; wings uniformly blackish, attaching to base of tibia; HF 65% of Tib; posterior margin of interfemoral membrane with bristle-like hairs. Only one specimen known (adult ♀). Sexual dimorphism: no information. Pelage dense; mid-dorsal hairs ca. 5 mm. Dorsal pelage originally described by Aellen & Brosset (1968) as dark brown with pale auburn at tip; dried hairs are now very dark brown with paler tip. Ventral pelage, originally described as grey, is now greyish; hairs brown with greyish tip. Face uniformly brown. Muzzle with naked skin dark brown. Ears dark brown, subtriangular with rounded tip, relatively short for an African *Myotis* (27% of FA). Tragus narrow, relatively long (ca. 60% of E). Wings uniformly blackish (without markings); attaching to base (distal end) of tibia. Tibia dorsally and

ventrally naked. Hindfoot relatively long (65% of Tib); claws long and robust. Calcar probably extending only half-way to tip of tail, but this needs confirmation. Interfemoral membrane blackish, dorsally naked except for short, straight hairs that protrude slightly beyond the posterior margin from the heel to ca. three-quarters of distance to tip of tail. Tail with two vertebrae protruding beyond interfemoral membrane.

Skull small and delicate. Braincase comparatively low; profile of forehead region (viewed laterally) weakly concave (Figure 147c). Sagittal crest absent. Anterior palatal emargination wide. Anterior and middle upper premolars in toothrow, both very much smaller than the posterior upper premolar (Figure 150g). The anterior premolar, on each side, is apparently slightly lower than the middle premolar, and smaller in crown area. The mandibles are missing and there are no recorded data for the lower teeth.

Geographic Variation No information.

Similar Species Three other sub-Saharan *Myotis* have uniformly coloured wings (Table 29, p. 691):

Myotis bocagii. Dorsal pelage pale to bright rufous, coppery-red to dark rusty-brown; hairs tricoloured (*M. b. bocagii*) or bicoloured (*M. b. cupreolus*). Wings attaching to base of first toe. Hindfoot relatively shorter (47–60% of tibia). Skull with profile of forehead region moderately to strongly concave.

M. scotti. Dorsal pelage shiny coppery-brown; hairs dark brown with terminal third coppery-brown. Wings attaching to base of first toe. Hindfoot relatively short (36% length of tibia). Ethiopia.

M. tricolor (sometimes). Larger (FA: 47–53 mm).

Distribution Known only from the type locality at Loudima, Congo, in the Southern Rainforest–Savanna Mosaic very close to the Rainforest BZ.

Myotis dieteri

Habitat An area where the primary forest was degraded and partly replaced by patches of savanna, and where limestone caves and a river are present (Aellen & Brosset 1968).

Abundance Probably rare (see Conservation).

Remarks As Aellen & Brosset (1968) noted, *M. dieteri* has characters common to species of *Myotis* previously placed in the subgenus *Leuconoe*, which forage over water. These include the attachment of the wing higher up than the base of the first toe, the relatively large hindfoot and long claws, short calcar, short ear and narrow tragus (Fenton & Bogdanowicz 2002). The holotype was taken from a cave, which has its opening on the side of a hill, only ca. 100 m above the valley of the Loudima R. (Adam & Le Pont 1974). From the narrow opening of the cave, a steep slope leads inwards to a lenticular cavern ca. 10 m in diameter and 2 m high at its highest place. The cave was occupied by ca. 100 bats of which the majority were *Rhinolophus landeri landeri* as well as numerous *Nycteris macrotis macrotis*; the cave appeared to be a

permanent day-roost for *N. macrotis* and *R. landeri* because both species were present each time the cave was visited. Furthermore, young bats of both of these species had been observed in this cave. In contrast, there was only a small number of *M. dieteri* and the holotype was the only individual collected. *Myotis dieteri* was not found in the cave on other occasions, nor was it found in four other caves in the Loudima-Kimongo region, nor in 40 other caves in Congo, which were investigated by Adam & Le Pont (1974).

Conservation IUCN Category: Data Deficient.

Only one specimen known, and only a small number have ever been seen (on only one occasion), in only one of 45 caves investigated over a period of ca. seven years (Adam & Le Pont 1974). Furthermore, not recorded from ten localities in nearby Mayombe and lower Kouilou regions of Congo, where 80 specimens (of 14 other species) were collected by Dowsett *et al.* (1991). Also, not recorded from Haut-Ivindo region of Gabon where 1732 individuals (27 species) were captured, from caves and by mist-netting, by Brosset (1966), nor from Kikwit (05° 13'S, 18° 49'E, DR Congo) where 538 specimens (18 species) were collected in 1995 (Van Cakenberghe *et al.* 1999). Consequently, Happold (2005) suggested it should be classified as Critically Endangered.

Myotis emarginatus GEOFFROY'S MYOTIS

Fr. Murin à oreilles échancrées; Ger. Wimperfledermaus

Myotis emarginatus (E. Geoffroy, 1806). Ann. Mus. Natn. Hist. Nat. Paris 8: 198. Charlemenont, Givet, Ardennes, France.

Taxonomy Originally *Vespertilio emarginatus*. Synonyms: ten (none in Africa). Subspecies: three. Molecular evidence suggests *M. emarginatus* is closely related to *M. welwitschii* (Ruedi & Mayer 2001). Chromosome number (Spain): 2n = 44; aFN = 50 (Pérez-Suárez *et al.* 1991). In Czechoslovakia, 2n = 44; aFN = 52 (Zima 1978).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped;

pelage not frizzled; FA: 39–43 mm; dorsal hairs tricoloured; wings uniformly greyish-brown without markings, attaching to base of first toe; HF 43–54% of Tib; posterior margin of interfemoral membrane without fringe of bristle-like hairs; ear with uniquely deep notch in outer margin. Sexes similar. Pelage dense, fairly woolly; mid-dorsal hairs 6–8 mm. Dorsal pelage greyish-brown to bright rusty-brown; hairs tricoloured, straw-yellow with grey base and tip of the dorsal colour. Ventral pelage slightly to considerably paler than dorsal pelage (yellowish-grey to pale rufous); hairs bicoloured,

basal half dark grey or dark greyish-brown. Juveniles darker and greyer; dorsal hairs less conspicuously tricoloured. Muzzle hairy, reddish-brown. Ears greyish-brown; relatively long for an African *Myotis* (ca. 40% of FA); outer margin with conspicuous angular notch ca. two-thirds from base (deeper than in other *Myotis* with notched ears) (Figure 149e). Tragus lancet-shaped, bluntly pointed; just over half of E (almost reaches notch). Wings uniformly greyish-brown without markings, naked; attaching to base of first toe. Tibia with dorsal surface hairy, ventral surface with sparse hairs. Hindfeet relatively short (43–54% of tibia, $n = 12$); toes with long claws and some long hairs. Calcars straight, extending ca. half-way to tip of tail. Interfemoral membrane greyish-brown; not covered by hairs; posterior margin with sparse, straight, soft hairs but no distinct fringe of curved bristle-like hairs. Terminal vertebra protruding beyond interfemoral membrane.

Skull of medium size for an African *Myotis*, fairly delicate. Braincase high; profile of forehead region (viewed laterally) strongly concave. Sagittal crest absent anteriorly, weakly developed posteriorly. Upper incisors subequal in crown area (cf. *M. nattereri*). Middle upper premolar reduced (slightly higher than cingulum of anterior premolar); within toothrow; anterior premolar not in contact with posterior premolar.

Geographic Variation None in Africa where only the nominate subspecies (*M. e. emarginatus*) occurs (Gaisler 1983).

Similar Species Three other *Myotis* with FA <45 mm occur in NW Africa (Table 29, p. 691):

Myotis capaccinii. Dorsal pelage medium to pale brownish-grey, silky; hairs bicoloured. Hindfoot larger (12–15 mm; 70–83% of tibia). Wing-membrane attaching to tibia well above heel. Interfemoral membrane covered by downy pelage. Outer edge of tibia hairy. Notch in posterior margin of ear shallow.

Myotis emarginatus

M. mystacinus. FA shorter (33–37 mm). Dorsal hairs bicoloured. Muzzle not hairy, naked skin blackish. Wings dark brown. Notch in posterior margin of ear shallow.

M. nattereri. Dorsal pelage greyish-brown; hairs bicoloured. Interfemoral membrane with dense fringe of bristle-like hairs between tip of each calcar and tail. Notch in posterior margin of ear comparatively shallow. Tragus longer (notably more than half of E).

Distribution In Africa, recorded mainly from the Mediterranean Coastal and Afromontane–Afroalpine BZs of the northern Maghreb in NW Africa. Recorded from the Middle Atlas, Rif Mts and Bni Snassen in Morocco, from the coastal zone and neighbouring part of the Tell Atlas in Algeria, extending into the northern mountains of Tunisia (Vaughan *et al.* 1977, Aulagnier & Thévenot 1986, Kowalski & Rzebik-Kowalska 1991). Extraliminally: S Europe northwards to the Netherlands and S Poland, and eastwards through Israel and Lebanon to Uzbekistan and E Iran.

Habitat Recorded from the coast to mountainous areas. In Europe, prefers limestone areas with caves as well as warm regions with woodlands, parks, gardens and water. No details available for Africa.

Abundance With few small colonies, NW African populations appear scarce by comparison with S Europe, where maternity colonies may comprise up to 1000 ♀♀.

Adaptations Aspect ratio low; wing-loading very low; wing-tip short and rounded (Norberg & Rayner 1987). Flight predicted to be slow with high manoeuvrability. Can hover, and does so while foraging. In winter, roosts in dark places in caves and mines with temperatures up to 12 °C and only rarely below 6 °C; individuals hang from ceilings or walls (and, rarely, disappear into crevices). In summer, also roosts in caves and mines; maternity roosts are warm, sometimes lighted and confined to elevations between 200–500 m. Avoids roosts in which temperature is likely to become too high. Predominantly sedentary; movements usually within 40 km (largest recorded 160 km). Breeding colonies have been found associated with *Rhinolophus ferrumequinum* in Tunisia (Vaughan *et al.* 1977), *R. euryale*, *R. blasii* and *Miniopterus schreibersii* in Algeria (Kowalski & Rzebik-Kowalska 1991), and *R. ferrumequinum*, *R. euryale*, *M. schreibersii* and *Myotis capaccinii* in Morocco (Brosset 1958). Torpid individuals were found in winter in Algeria (Kowalski & Rzebik-Kowalska 1991).

Foraging and Food Forages mainly by gleaning (from branches, foliage, walls and the ground), and less often by slow-hawking; occasionally hovers in front of foliage and walls (Krull *et al.* 1991). Forages late after dusk, in woodlands (mainly around the edges and in clearings) and often over water. Forages as far as 10 km from maternity roosts. Feeds mainly on spiders, and also on flies (Diptera: Muscoidea) moths and caterpillars (Lepidoptera) (Bauerova 1986, Krull *et al.* 1991, Beck 1995).

Echolocation Highly variable depending on activity and habitat; these data refer to cruising calls in the main habitat. Search-phase call-shape (close to foliage) steep linear FM. Start-frequency 110 kHz; end-frequency 39 kHz; peak-frequency 65 kHz; call-duration 2.6 ms; inter-call interval 26–32 ms (Barataud 2005).

Social and Reproductive Behaviour Roosts singly or in colonies; in Algeria, torpid ♂♂ and ♀♀ roosting singly were found in winter; and a colony of ca. 20 (of which five were non-pregnant ♀♀) was found in May (Kowalski *et al.* 1986). In Europe, mating starts in autumn. In winter, ♂♂ and ♀♀ roost together in colonies. The sexes segregate in Apr–May when pregnant ♀♀ establish maternity colonies; these may contain 20–200 adult ♀♀; up to 3000 in W France (Arthur & Lemaire 1999). In these colonies, ♀♀ huddle in very tight clusters. In summer, ♂♂ roost singly (Schober & Grimmberger 1987).

Reproduction and Population Structure Litter-size (Algeria): one (n = 2) (Brosset 1958, Kowalski *et al.* 1986). In Algeria, the reproductive chronology is assumed to be restricted seasonal monoestry (as in Europe); records of pregnant ♀♀ in mid-May, a ♀ with full-term foetus in early Jun, lactating ♀♀ and an almost-volant juvenile in early Jul, indicate that births probably occur in first half of Jun (Kowalski *et al.* 1986). Juveniles become volant in early Jul, but are weaned sometime later. Maximum life-span: 16 years.

Predators, Parasites and Diseases Ectoparasites include a flea *Rhinolophopsylla unipunctata* (Siphonaptera: Ischnopsyllidae) because *M. emarginatus* often roosts in tight association with rhinolophid bats, which are the principal hosts of this flea (Beaucournu & Kowalski 1985).

Conservation IUCN Category: Least Concern (based largely on extralimital data).

Because NW African populations are presumably numerically small, urgent conservation should focus on the main identified roosts and bodies of water nearby.

Myotis morrisi MORRIS'S MYOTIS

Fr. Murin d'Éthiopie; Ger. Morris' Mausohr

Myotis morrisi Hill, 1971. Bull. Brit. Mus. (Nat. Hist.) Zool. 21: 43. Mouth of Didessa River, Walaga, Blue Nile Gorge, Ethiopia.

Taxonomy Synonyms: none. Chromosome number: not known.

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 45, 47 mm; dorsal pelage orange-brown; wings blackish with yellow to orange markings (particoloured); ventral pelage unicoloured. Sexes similar. Pelage dense, fairly woolly; mid-dorsal hairs ca. 7 mm. Dorsal pelage bright orange-brown; hairs tricoloured, creamy-white with basal quarter dark brown and tip orange-brown. Ventral pelage dull creamy-white to orange-beige, chin and flanks slightly darker; hairs unicoloured (cf. all other *Myotis* from Africa). Muzzle pink. Ears pink basally shading to brown at tip; of medium relative length for an African *Myotis* (35–37% of FA, n = 2); outer margin with slight notch. Tragus pink, bluntly pointed, ca. half of E. Wings mainly dark blackish-brown but lightly pigmented with yellow along leading edge and in narrow band posterior to the forearm, and between the body and a line roughly joining the elbow and ankle (Figure 149g). Wings naked except for narrow band on dorsal surface adjacent to body; wing-membrane attaching to base of first toe. Tibia hairy. Hindfoot relatively short (45–49% of Tib, n = 2). Calcar extending half of distance to tip of tail. No postcalcareal lobe. Interfemoral membrane yellow; dorsal

pelage extending over distal half of membrane; no fringe of bristle-like hairs on posterior edge of membrane. Terminal vertebra may or may not protrude beyond membrane.

Skull of medium size for an African *Myotis*, fairly delicate. Braincase high, profile of forehead region (viewed laterally) strongly concave. No sagittal crest. Middle upper premolar reduced (reaching only slightly above cingulum of anterior premolar and slightly less than half crown area of anterior premolar); slightly to almost fully displaced labially but anterior and posterior premolars not in contact. Anterior and middle lower incisors with four cusps. Anterior palatal emargination very narrow (cf. *M. bocagii*) (Figure 150e).

Geographic Variation None recorded.

Similar Species Only two other *Myotis* in Africa have wings with a pattern in contrasting colour (Table 29, p. 691):

Myotis welwitschii. Larger (FA: 52–60 mm). Wing colours black and orange; pattern very conspicuous. Ventral hairs bicoloured.

M. tricolor (sometimes). Wing colours, if pattern is present, black and dark reddish-brown; pattern inconspicuous. Ventral hairs tricoloured.

Distribution Endemic to Africa. Only known from two specimens and two localities in the Sudan Savanna BZ: the type locality in the Blue Nile Gorge, Ethiopia, and Numan, Nigeria (Hill & Morris 1971, Hill *et al.* 1988). Presumably widespread across the Sudan Savanna BZ.

Habitat A lowland species of dry scrub. The holotype was found hunting over the Blue Nile R. in an area of riverine scrub and maize fields. The Nigerian specimen was taken near the Benue R., in a region of short grass and *Acacia* bush, with some silk-cotton trees (Hill *et al.* 1988).

Abundance Very rare?

Remarks Forages at moderate height (1–3 m). Nothing else is known about the habits of this species.

Conservation IUCN Category: Data Deficient.

Only two specimens and two widely separated locations known.

Myotis mystacinus WHISKERED MYOTIS (WHISKERED BAT)

Fr. Murin à moustaches; Ger. Kleine Bartfledermaus

Myotis mystacinus (Kuhl, 1817). Die Deutschen Fledermäuse. Hanau, p. 15. Germany.

Taxonomy Originally *Vespertilio mystacinus*. Synonyms: 15 (none in Africa). Subspecies: four recognized by Benda & Tsytulina (2000) of which probably only one occurs in Africa. According to von Helversen *et al.* (2001), Moroccan specimens represent the nominate subspecies, *M. m. mystacinus*. However, they could represent the recently identified *M. m. occidentalis* from the Iberian Peninsula (Benda & Tsytulina 2000), but this needs confirmation. Chromosome number (Switzerland): 2n = 44; aFN = 50 (Bovey 1949).

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 33–37 mm; dorsal hairs bicoloured; wings uniformly dark brown, attaching to base of first toe; HF 40–52% of Tib; posterior margin of interfemoral membrane without fringe of bristle-like hairs. The smallest species of *Myotis* in Africa. Sexes similar. Pelage dense, somewhat shaggy, without sheen; mid-dorsal hairs 6–8 mm. Dorsal pelage greyish-brown; hairs bicoloured, black or blackish-brown with greyish-brown at tip. Ventral pelage grey to creamy-white; hairs

bicoloured, dark blackish-brown with grey to creamy-white at tip. Muzzle blackish; upper lip fringed with stiff hairs. Ears blackish-brown; relatively long for an African *Myotis* (34–45% of FA, n = 8); outer margin with shallow notch. Tragus sickle-shaped, bluntly pointed; ca. half of E. Eyes small, partly concealed by pelage. Wings uniformly dark brown without markings; naked; attaching to base of first toe. Tibia naked or almost naked dorsally and ventrally. Hindfoot relatively short (40–52% of Tib, n = 12); toes with some long hairs. Calcar extending less than half distance to tip of tail. Postcalcareal lobe absent or weakly developed. Interfemoral membrane dark brown; no fringe of bristle-like hairs on posterior margin (Figure 149c). Terminal vertebra of tail protruding beyond interfemoral membrane.

Skull small and delicate. Braincase high, profile of forehead region (viewed laterally) strongly concave. No sagittal crest. Middle upper premolar ca. half height and half crown area of anterior premolar; usually both in tooththrow, sometimes both slightly displaced lingually, anterior premolar not in contact with posterior premolar.

Geographic Variation None in Africa (see Taxonomy).

Myotis mystacinus

Similar Species Three other *Myotis* with FA <45 mm occur in NW Africa (Table 29, p. 691):

Myotis capaccinii. FA longer (39–43 mm). Dorsal pelage medium to pale brownish-grey. Hindfoot longer (12–15 mm; 70–83% of tibia). Wings attaching to tibia well above heel. Interfemoral membrane covered by downy pelage.

M. emarginatus. FA longer (39–43 mm). Dorsal hairs tricoloured. Muzzle hairy and reddish-brown. Wings greyish-brown. Notch in posterior margin of ear deep.

M. nattereri. FA longer (37–42 mm). Posterior margin of interfemoral membrane with dense fringe of bristle-like hairs between tip of each calcar and tail. Muzzle reddish-pink.

Distribution In Africa, only known from mountainous parts of the Mediterranean Coastal and Afromontane–Afroalpine BZs, and marginally from the adjacent Sahara Arid BZ, in N Morocco. Recorded from five localities: the Rif Mts, the Middle Atlas and the High Atlas (central northern slope and south-eastern piedmont) (Benda *et al.* 2004d). Extralimittally: widespread from Ireland and Scandinavia, through Iran and the Himalayas to China. Absent from the southern Iberian Peninsula.

Habitat Very little information for Africa. Several specimens were mist-netted over rivers in forests of sparse Cork Oak (*Quercus suber*), Green Oak (*Q. ilex*) or Atlas Cedar (*Cedrus atlantica*), up to 1780 m (Benda *et al.* 2004d). One record is from an oasis on the southern slope of the High Atlas Mts (Aulagnier & Destre 1985), and another is from an arid area (Panouse 1953). In Europe, found most often in forests, gardens, parks and riverine habitats (Schober & Grimmberger 1987). In former USSR, it favours deserts, semi-deserts and the lower and middle mountain zones (Strelkov 1983).

Abundance Apparently very rare in NW Africa (<25 specimens recorded); rare in S Europe but abundance increases further north.

Adaptations Aspect ratio low; wing-loading very low; wing-tip short and rounded (Norberg & Rayner 1987). Flight highly manoeuvrable; open-field flight estimated at ca. 4.4 m/sec (Baagøe 1987), which is comparatively very slow. In Morocco, day-roosts include behind bark of *Tamarix aphylla* in an oasis (Aulagnier & Destre 1985) and in little openings in the structure of a bridge (Ibáñez 1988). In Europe, roosts mainly in buildings in summer, and mainly in caves, mines and cellars in winter. Hangs from ceilings and walls and sometimes wedges itself in cracks and crevices. Hibernates from Oct–Mar in Europe; presumably for a shorter period in Morocco. Occasionally migrates; longest recorded movement 240 km (Schober & Grimmberger 1987).

Foraging and Food Forages by gleaning (from branches or from the ground) and by slow-hawking. In Britain, Jones (1993) has seen this species foraging around tops of fairly tall trees and sometimes flying into the foliage. In Switzerland and England, feeds mainly on Diptera (including Tipulidae, Chironomidae, Anisopodidae, Culicidae), spiders (Arachnida) and moths (Lepidoptera) (Vaughan 1977, Beck 1995).

Echolocation Echolocation calls (Europe) highly variable depending on activity and habitat; these data refer to cruising calls in the main habitat. Search-phase call-shape (close to foliage) steep linear FM. Start-frequency 105 kHz; end-frequency 33 kHz; peak-frequency 62 kHz; call-duration 2.7 ms; inter-call interval 50–80 ms (Jones 1993, Barataud 2005).

Social and Reproductive Behaviour Roosts singly or in groups. Hibernates in colonies, up to 600 individuals in France (Arthur & Lemaire 1999); ratio of ♂♂ : ♀♀ in hibernacula is male-biased. Sexes segregate in May; pregnant ♀♀ establish maternity colonies (10–70 individuals), which they occupy in summer; ♂♂ appear to be solitary in summer (Schober & Grimmberger 1987).

Reproduction and Population Structure Litter-size (Europe): one. In Europe, the reproductive chronology is restricted seasonal monoestry with mating from autumn to spring (sometimes in winter-roosts); births in Jun or early Jul; lactation for ca. six weeks. Juveniles begin foraging within six weeks. Females leave maternity colonies in late Aug (Schober & Grimmberger 1987). Maximum life-span: 23 years.

Predators, Parasites and Diseases Predators occasionally include Pharaoh Eagle-owls *Bubo ascalaphus* (Aulagnier 1989). Ectoparasites (Morocco) include a tick *Argas transgarepinus* (Acari: Argasidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern (based mainly on extralimittal data).

NW African populations, however, are scarce and vulnerable. Pesticides and logging are presumably the main local threats.

***Myotis nattereri* NATTERER'S MYOTIS (NATTERER'S BAT)**

Fr. Murin de Natterer; Ger. Fransenfledermaus

Myotis nattereri (Kuhl, 1817). Die Deutschen Fledermäuse. Hanau, pp. 14, 33. Hanau, Hessen, Germany.

Taxonomy Originally *Vespertilio nattereri*. Synonyms: five; none in Africa. Subspecies: two; only the nominate occurs in Africa (Koopman 1994). Chromosome number (Spain): $2n = 44$; $aFN = 50$ (Pérez-Suárez *et al.* 1991). Since this profile was submitted, *escalerai* Cabrera, 1904, formerly included in *M. nattereri*, was restored to specific status by Ibáñez *et al.* (2006), and García-Mudarra *et al.* (2009) conclude that a sister species is the only *Myotis* of the *nattereri* group in North Africa.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 37–42 mm; dorsal hairs bicoloured; wings uniformly dark greyish-brown, attaching to base of first toe; HF 46–60% of Tib; margin of interfemoral membrane with fringe of bristle-like hairs; tragus just over two-thirds of E. Sexes similar. Pelage dense, silky; mid-dorsal hairs 6–8 mm. Dorsal pelage greyish-brown; hairs bicoloured, basal half blackish-brown, terminal half greyish-brown. Ventral pelage pale grey to off-white; hairs bicoloured, blackish-brown with whitish tip. Muzzle almost naked, reddish-pink; upper lip with long hairs. Ears dark greyish-brown; relatively long for an African *Myotis* (mean E ca. 40% of mean FA); outer margin with slight notch. Tragus long, slender, bluntly pointed; notably more than half of E (cf. ca. half in other North African species), reaching beyond notch in ear. Wings uniformly dark greyish-brown without markings; attaching to base of first toe. Tibia not hairy. Hindfoot of medium relative length (46–60% of Tib, $n = 22$); toes with long hairs. Calcar S-shaped, reaching half of distance to tip of tail. Interfemoral membrane dark greyish-brown; naked; posterior margin with dense fringe of bristle-like hairs (Figure 149b). Terminal vertebra of tail sometimes protruding beyond interfemoral membrane.

Skull small. Braincase high, profile of forehead region (viewed laterally) strongly concave. No sagittal crest. Outer upper incisor with crown area twice that of inner upper incisor (cf. *M. emarginatus*). Middle upper premolar more than half height of anterior premolar and ca. three-quarters of its crown area; within tooththrow.

Geographic Variation None in Africa.

Similar Species Three other *Myotis* with FA <45 mm occur in NW Africa (Table 29, p. 691):

Myotis capaccinii. Dorsal pelage pale brownish-grey. Hindfoot longer (12–15 mm; 70–83% of tibia). Wings attaching to tibia well above heel. Interfemoral membrane covered by downy pelage; margin without fringe of bristle-like hairs. Tragus shorter (5–9 mm), ca. half of E.

M. emarginatus. Dorsal pelage reddish-brown; hairs tricoloured. Posterior margin of interfemoral membrane without dense fringe of bristle-like hairs. Notch in posterior margin of ear deep. Dorsal hairs tricoloured. Tragus shorter (less than half of E).

M. mystacinus. FA shorter (33–37 mm). Posterior margin of interfemoral membrane without dense fringe of bristle-like hairs. Muzzle blackish.

Distribution In Africa, recorded from the Mediterranean Coastal BZ of Morocco and Algeria, extending inland to the Afromontane–Afroalpine BZ (western High Atlas, Middle Atlas and Tell Atlas)

*Myotis nattereri*

(Brosset 1963, Aulagnier & Thévenot 1986, Ibáñez 1988, Kowalski & Rzebik-Kowalska 1991, Benda *et al.* 2004d). Extraliminally: Europe (except northern Scandinavia) through Turkey, Israel and Iraq to Turkmenistan.

Habitat Predominantly an open woodland bat, attracted by open water and marshland (some Algerian specimens were mist-netted over a stream in an oak forest [Gaisler & Kowalski 1986]). Also recorded in Mediterranean maquis and occasionally in towns. Recorded from sea level to 1200 m.

Abundance Based on paucity of records and limited area of suitable habitat, population numbers in NW Africa are probably low. However, one cave in Algeria contained a cluster of ca. 300 individuals (Kowalski *et al.* 1986).

Adaptations Aspect ratio low; wing-loading very low (Norberg & Rayner 1987). Flight predicted to be slow with high manoeuvrability; speed in open estimated to be ca. 4.5 m/sec (Baagøe 1987), which is comparatively very slow. In summer, roosts in hollow trees, behind bark, sometimes in cracks under bridges and cracks in buildings. In winter, hibernates in cool and damp caves, cellars and mines; hangs freely from ceilings or walls, or squeezes into small crevices. In Europe, hibernates in Oct–Apr. Sedentary; longest recorded movement is 90 km.

Foraging and Food Forages by slow-hawking and by gleaning (without landing) from vegetation (Arlettaz 1996b, Siemers & Schnitzler 2000). Emergence peaks one hour after sunset, and the last bats return to the roost half an hour before sunrise. Forages up to 3 km from the roost, in woodlands, near hedges and road-side vegetation, and over sheltered stretches of water. In Israel, feeds mainly on diurnal Diptera (Whitaker *et al.* 1994), but Coleoptera, Opilions, spiders and caterpillars are also important (Shiel *et al.* 1991, Beck 1995, Vaughan 1997).

Echolocation Echolocation calls highly variable depending on activity and habitat; these data refer to cruising calls in the main habitat. Search-phase call-shape (2–3 m from obstacles) steep linear FM. Start frequency 120 kHz; end-frequency 14 kHz; peak-frequency 55 kHz; call-duration 2–4 ms; inter-call interval 70–90 ms (Jones 1993, Siemens & Schnitzler 2000, Barataud 2005).

Social and Reproductive Behaviour Roosts singly or in groups or small colonies. Mating occurs in autumn. In winter, hibernates singly or in small groups; group-members roost in clusters. Sexes

segregate in spring when pregnant ♀♀ establish maternity colonies containing 20–70 individuals, rarely up to 300; summer colonies change their roosts quite often. In Algeria, a colony of ca. 300 individuals, huddled together in a dense cluster on the ceiling of a cave, was found in Apr; a sample contained 14 ♂♂ with small testes and eight ♀♀, each with a small foetus (Kowalski *et al.* 1986).

Reproduction and Population Structure Litter-size (Algeria): one (n = 8) (Kowalski *et al.* 1986). In Europe, the reproductive chronology is restricted seasonal monoestry with mating from autumn to spring; births in summer (Jun–Jul); lactation for six weeks. Juveniles volant and starting to forage at ca. three weeks. Maximum life-span: 20 years.

Predators, Parasites and Diseases Ectoparasites include a flea *Ischnopsylla hispanica* (Siphonaptera: Ischnopsyllidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern (based mainly on extralimital data).

Status should be re-evaluated in NW Africa where populations are threatened by intense logging and pesticides.

Myotis punicus MAGHREB MYOTIS

Fr. Murin du Maghreb; Ger. Maghreb-Mausohr

Myotis punicus Felten, Spitzenberger and Storch, 1977. Senckenberg. Biol. 58: 39. Cap Bon, Tunisia.

Taxonomy Originally *Myotis blythii punicus*. Synonyms: none. *Myotis blythii* and *Myotis myotis* are two closely related, sibling species, which contain several forms of controversial taxonomic status. As these two species are essentially distinguished by size, several

intermediate forms have been alternatively attributed to either species (see reviews in Strelkov 1972, Felten *et al.* 1977, Arlettaz *et al.* 1997b, Topál & Ruedi 2001). The Maghreb Myotis illustrates this problem: it has been considered either as a smaller version of *M.*

myotis (Brosset 1960b, Arlettaz *et al.* 1997b) or as a larger subspecies of *M. blythii* (Bogan *et al.* 1978, Corbet & Hill 1991, Koopman 1994). However, recent molecular work based on microsatellite and mitochondrial DNA has shown that the North African taxon is genetically very distinct from both species, and therefore warrants specific status (Castella *et al.* 2000). These authors suggest that the current distribution of *M. punicus* does not overlap with that of *M. myotis* or *M. blythii*, possibly because of competitive exclusion. Chromosome number: not known.

Description Medium-small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 54–62 mm; dorsal pelage bicoloured; wings uniformly brown, attaching to base of first toe; HF ca. 50% of Tib; posterior margin of interfemoral membrane naked. Females, on average, with slightly longer forearms than ♂♂. Pelage woolly, extending dorsally onto base of interfemoral membrane; mid-dorsal hairs 7–9 mm. Dorsal pelage medium to pale brown; hairs bicoloured, basal half dark grey. No distinctive white patch between the ears (cf. extralimital *M. blythii*; Arlettaz *et al.* 1991). Ventral pelage creamy-white; hairs bicoloured, basal half grey, terminal half creamy-white. Juveniles darker and greyer dorsally, white ventrally. Muzzle with naked area brownish-red. Ears brownish-red, relatively long for an African *Myotis* (42.5 [39–46]% of FA, $n = 116$). Tragus straight, narrow, of medium relative length (ca. 50% of E). Wings uniformly brown, attaching to base of first toe. Tibia naked. Hindfoot of medium relative length (50 [47–56]% of Tib). Calcar relatively short (reaching one-third of distance to tip of tail). Postcalcarea lobe vestigial or absent. Interfemoral membrane brownish-red; naked; posterior margin without fringe of bristle-like hairs. Tail almost completely enclosed by membrane.

Skull comparatively large, rostrum robust. Braincase comparatively low; profile of forehead region (viewed laterally) moderately concave. Sagittal crest strongly developed. Middle upper premolar ca. half height and crown area of anterior premolar or less; within toothrow or somewhat displaced lingually, anterior and posterior premolars separated.

Geographic Variation None recorded.

Similar Species None: all other *Myotis* known to occur in North Africa are much smaller (FA: <45 mm) and lighter (<13 g) (Table 29, p. 691).

Distribution In Africa, apparently only found in the Mediterranean Coastal and Afromontane–Afroalpine BZs in NW Africa (Morocco, Algeria and Tunisia) and very marginally from the Sahara Arid BZ in NW Libya. Its African distribution is limited to the south and to the east by the Saharan and Libyan deserts, respectively. Map based on Aulagnier & Th  venot (1986), Castella *et al.* (2000), Han  k & Elgadi (1984), Kowalski & Rzebik-Kowalska (1991) and Qumsiyeh (1983). Extraliminally: the Mediterranean islands of Corsica, Sardinia and Malta. That *M. punicus* is endemic to western North Africa and these adjacent islands is indicated by DNA data (Castella *et al.* 2000, Top  l & Ruedi 2001).

Myotis punicus

Habitat In Africa, widespread from the coastal zones to the high mountains in the Atlas and found from forested to more arid areas. Because of its foraging habits, probably prefers sparsely forested, semi-open and desert-like habitats.

Abundance Widespread and probably abundant throughout the Mediterranean Region of North Africa. The most numerous species of bat in the caves of N Algeria (Kowalski & Rzebik-Kowalska 1991 as *M. blythii*). Maternity colonies of several hundreds to thousands of ♀♀ not uncommon.

Adaptations Wing morphology: no information. Roosts by day in caves and abandoned mines. In the warmer months, often shares roosts with other cave-dwelling bats such as *Rhinolophus* spp. or *Miniopterus schreibersii*, but no mixed-species groups have been found in winter (Kowalski & Rzebik-Kowalska 1991). In winter, moves to more concealed quarters and enters into deep torpor. Extent of seasonal movements between winter and summer-roosts largely unknown.

Foraging and Food Rather adaptable; hunts probably mostly on bare grounds in forests without understorey, and in open, more arid habitats as well. Probably searches for prey by flying close to the ground, drops on it and eats it on the wing (Arlettaz 1996a, as *M. myotis*). In North Africa, its diet consists mainly of crickets, beetles, spiders; it also includes scorpions (Arlettaz *et al.* 1997a).

Social and Reproductive Behaviour Roosts singly, or in groups ranging from two to several thousands. During the mating period (Aug–Nov), ♂♂ establish small, individual territories in the ceilings of the caves to attract ♀♀ for copulation (Hor    ek & Gaisler 1985–86, as *M. blythii*). Each ♂ then maintains a small harem of 1–4 ♀♀. Several pairs were seen hanging together, the ♂ touching the ♀ with the ventral surface of his body (Kowalski & Rzebik-Kowalska 1991).

1991). In Nov, a colony of ca. 50 was observed, but none of the caves or mines under observation served as winter hibernacula; only a few individuals, roosting singly or in clusters of up to five individuals, were found during this time (Kowalski & Rzebik-Kowalska 1991). In summer, pregnant ♀♀ establish maternity colonies in the warmer caves and mines; these often contain hundreds or thousands of adult ♀♀. Nulliparous ♀♀ and a few ♂♂ also roost with these colonies; the adult ♂♂ usually roost away from the maternity colonies.

Reproduction and Population Structure Litter-size (Algeria): one (n = 5) (Kowalski *et al.* 1986, as *M. blythi*). In N Algeria, the reproductive chronology is restricted seasonal monoestry with spermatogenesis beginning in early Mar in mature ♂♂ and in Jun in ♂♂ breeding for the first time; mating from Aug to early Nov; births from mid-Apr to mid-May or sometimes early Jun (Kowalski *et al.* 1986). One banded ♀ mated in the year of her birth (Kowalski & Rzebik-Kowalska 1991).

Predators, Parasites and Diseases Predators include owls (Pharaoh Eagle-owl *Bubo ascalaphus*, Barn Owl *Tyto alba*, Tawny Owl *Strix aluco* and occasionally Little Owl *Athene noctua* [Aulagnier 1989]), small carnivores (e.g. *Martes foina*, *Genetta genetta*, *Felis libyca*) and a snake *Coluber hippocrepis* (Hammer & Arlettaz 1998). Ectoparasites include bat-flies (Diptera; Nycteriibidae) and mites *Spinturnix* sp. (Acari: Spinturnicidae). No known diseases have been reported for these bats.

Conservation IUCN Category: Near Threatened (based on African and extralimital data).

Although widespread and apparently abundant in North Africa, the area of occupancy is fairly restricted, and maternity colonies are very vulnerable to disturbance by humans. Throughout North Africa, dried bats are used in traditional medicine, and this species is sometimes heavily hunted to provision local markets. Almost meets criteria for Vulnerable.

Myotis scotti SCOTT'S MYOTIS

Fr. Murin de Scott; Ger. Scotts Mausohr

Myotis scotti Thomas, 1927. Ann. Mag. Nat. Hist., ser. 9, 19: 554. Djem-Djem Forest, 40 miles west of Addis Ababa, Ethiopia, 8000 ft (2438 m).

Taxonomy Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears separated, not funnel-shaped; pelage not frizzled; FA: 37–41 mm; dorsal pelage coppery-brown; face with conspicuous dark 'mask'; wings uniformly dark brown; HF 43 (39–47)% of Tib; posterior margin of interfemoral membrane with bristle-like hairs. Not easily distinguished from *M. bocagii*. Sexes similar. Pelage dense, slightly woolly with silky sheen; mid-dorsal hairs ca. 7 mm. Dorsal pelage shiny coppery-brown; hairs bicoloured, dark brown with terminal third coppery-brown. Ventral pelage beige to off-white; hairs bicoloured, dark brown with whitish tip. Face and naked skin of muzzle are dark brown, creating a dark 'mask'. Ears dark brown; of medium relative length for an African *Myotis* (ca. 37% of FA; n = 3); outer margin without notch. Tragus straight, relatively short, 34% of E (n = 1). Wings uniformly dark brown without markings; attaching to base of first toe. Tibia hairy dorsally and ventrally. Hindfoot relatively short (43 [39–47]% of Tib, n = 3); toes with long hairs. Calcar reaching half distance to tip

of tail. Interfemoral membrane dark brown; posterior margin with numerous bristle-like hairs between ends of calcars and tip of tail. Tail fully enclosed by interfemoral membrane, or slightly projecting.

Skull small and delicate. Braincase comparatively high, profile of forehead region (viewed laterally) strongly concave. No sagittal crest. Upper canines very short, ca. 1.2 mm from cingulum to tip (cf. *M. bocagii*). Middle upper premolar ca. half height of anterior premolar or less, and ca. two-thirds of its crown area; within toothrow.

Similar Species Three other sub-Saharan *Myotis* have uniformly coloured wings (Table 29, p. 691):

Myotis bocagii. Dorsal pelage tricoloured in area of sympatry. Posterior margin of interfemoral membrane naked. HF 53 (47–60)% of Tib. Braincase comparatively low; profile of forehead region moderately to strongly concave. Upper canines longer (1.5–1.8 mm). Middle upper premolar larger (ca. half to three-quarters height of anterior premolar); usually displaced lingually. *M. dieteri*. Dorsal hairs dark brown with auburn tip. No mask. HF 65% of Tib. Skull with profile of forehead region weakly concave.

M. tricolor (sometimes). Larger (FA: 47–53 mm). Wings sometimes with faint black and dark reddish-brown pattern.

Distribution Endemic to Africa. Apparently confined to the Afromontane–Afroalpine BZ of the Ethiopian Highlands; occurs both sides of the Rift Valley. Recorded from only seven sites in SC Ethiopia (Largen *et al.* 1974, Yalden & Largen 1992).

Habitat Found in moist forested locations, in a range of altitudes from 1300–2500 m.

Abundance Rare, only 11 specimens known. Collecting in Ethiopia, 1968–75, yielded only one in a sample of 305 bats.

Remarks Canines short compared with other African *Myotis*. The type series of six roosted colonially in furled leaves of banana plants (Thomas 1927a). Based on morphology, predicted to forage by slow-hawking at low to medium heights above ground, and to feed on small insects. Two specimens were captured with a hand-held flick-net, while they were foraging at 1–3 m above ground, over low bushes near water.

Conservation IUCN Category: Vulnerable.

Known from only seven locations in a very restricted area of occupancy. As a forest species, it must be threatened by continuing human population increase and consequent deforestation, but no specific information is available.

Myotis tricolor TEMMINCK'S MYOTIS (TEMMINCK'S HAIRY BAT)

Fr. Murin tricolore; Ger. Dreifarb-Mausohr

Myotis tricolor (Temminck, 1832). In: Smuts, Enumer. Mamm. Capensium, p. 106. Cape Town, Cape Province, South Africa.

Taxonomy Originally *Vespertilio tricolor*. Synonyms: *loveni*. Subspecies: none. Chromosome number (Zimbabwe, South Africa): 2n = 44; aFN = 50 (Rautenbach *et al.* 1993).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; medium-sized for an African *Myotis* (FA: 47–53 mm); dorsal pelage coppery-brown to rufous; wings blackish-brown, sometimes with inconspicuous reddish-brown markings (i.e. sometimes particoloured); ventral hairs tricoloured. Sexes similar. Pelage dense, fairly woolly; mid-dorsal hairs 7–8 mm. Dorsal pelage coppery-brown to rusty-brown; hairs tricoloured, cream with grey to dark blackish-brown at base and coppery-brown to rufous (rusty-brown) at tip. Ventral pelage paler; hairs tricoloured, creamy-fawn with dark blackish-

brown at base and pale brown at tip. Muzzle brown, almost naked. Ears brown; of medium relative length for an African *Myotis* (34.9 [32–48%] of FA, n = 20); tip rounded; outer margin with slight emargination mid-way. Tragus length on average 56% of ear length. Wings of living Malawian individuals are dark blackish-brown with reddish-brown over the finger-bones and adjacent to body (Figure 149h): these markings are faint (cf. the striking black and orange markings of *M. welwitschii*). Elsewhere, the wings are reported to be dark blackish-brown with no mention of markings. Wings naked; attaching to base of first toe. Tibia naked ventrally, some hairs dorsally. Hindfoot of medium relative length (51.6 [47–58%] of Tib). Calcar straight, extending half-way to tip of tail. Interfemoral membrane reddish-brown; naked; posterior margin without fringe of bristle-like hairs. Tail fully enclosed by membrane.

Skull comparatively large and robust. Braincase high, profile of forehead region (viewed laterally) strongly concave. Sagittal crest

weakly developed or absent. Middle upper premolar reduced (reaching only slightly above cingulum of anterior premolar and much less than half crown area of anterior premolar), partly to fully displaced lingually, anterior and posterior premolars separated or in contact.

Geographic Variation None recorded.

Similar Species Only two other *Myotis* in Africa have wings with a pattern in contrasting colour (Table 29, p. 691):

Myotis welwitschii. Almost always larger (FA: 52–60 mm). Wing colours black and orange; pattern very conspicuous. Ventral hairs bicoloured.
M. morrisi. Wing colours black and yellow; pattern moderately conspicuous. Ventral hairs unicoloured.

Note: individuals of *M. tricolor* that have unpatterned wings are distinguished from other sub-Saharan species with unpatterned wings by their larger size (FA: 47–52 mm cf. <42 mm in *M. bocagii*, *M. dieteri* and *M. scotti*).

Distribution Endemic to Africa. Recorded, very disjunctly, mainly from the Afromontane–Afroalpine, Somalia–Masai Bushland, Zambezan Woodland, Highveld and South-West Cape BZs and from some parts of the Coastal Forest Mosaic BZ, from Ethiopia to South Africa, with isolated records from the Rainforest BZ (Western Region) in Liberia, and from the Southern Rainforest–Savanna Mosaic in SW DR Congo. The specimen from Bomi Wood Concession, Liberia, agrees well with *M. tricolor* from the eastern side of Africa (Koopman 1989), but its isolation invites investigation. However, there are similarly isolated records of *M. welwitschii* in West Africa.

Habitat Very varied. Ethiopia: montane habitats from 1590–2600 m (Largen *et al.* 1974). Kenya: rainforests, montane forests and

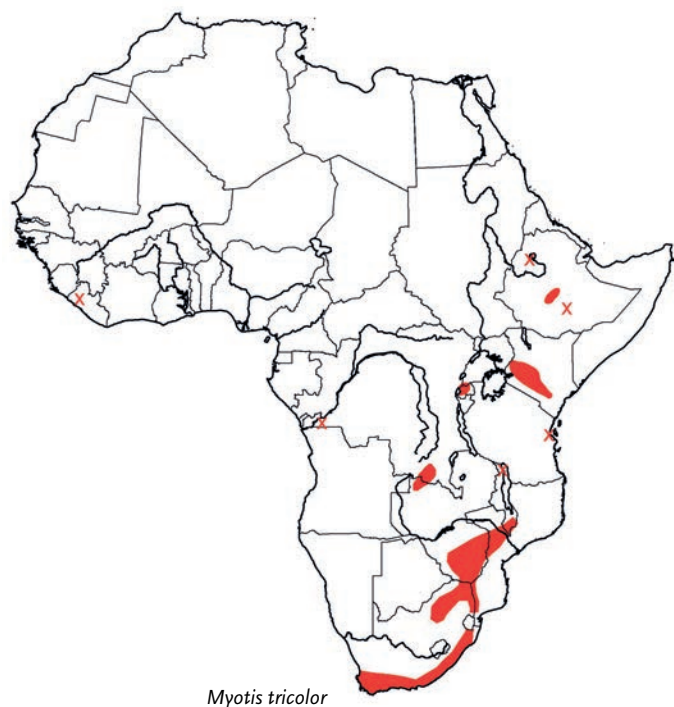

also much drier *Acacia–Commiphora* bushland and thicket. Tanzania: coastal forests (Cockle *et al.* 1998). Zambia: miombo woodland (Ansell 1978). Malawi: montane forest near large dam at 1450 m, miombo woodland at 480–500 m, and an ornamental garden with large trees and remnant riverine woodland near Shire and Ruvo rivers at 100 m (Harrison 1982, Happold & Happold 1997). South Africa: mainly woodland savanna habitats, but also drier grassland savannas, and montane habitats in the Drakensberg (Smithers 1983, Watson 1990b, Lynch 1994, Taylor 2000). All South African records are from regions with >500 mm annual rainfall (Rautenbach 1982) and the distribution is probably limited by rainfall and occurrence of suitably humid caves and mines (Smithers 1983, Bernard pers. obs.).

Abundance Uncertain. Appears to be uncommon or rare throughout geographic range (Koopman 1966, Happold & Happold 1997), except for South Africa where recorded from many localities in eastern parts, and in colonies of up to 2000 (Taylor, P. 1998, 2000).

Adaptations Aspect ratio low; wing-loading low (M. Happold pers. comm.). Flight very manoeuvrable; turns by banking (minimum radius of turn <25 cm) and by stalling-and-twisting; can take off from ground; not known to hover. Individuals in a 1×1×1 m enclosure were unable to complete more than two complete circuits/flight (3 bats, 10 flights each; M. Happold pers. comm.). Can scuttle over flat surfaces and climb well, moving wings and hindlimbs in alternation, sometimes with diagonal limb co-ordination. In South Africa, roosts by day in moist caves, mine-shafts and mine-adits; hangs freely from ceilings or clings in contact with walls. Often found in larger caves, usually ones containing pools of water, where disturbance is minimal (Roberts 1951, Herselman & Norton 1985). In parts of South Africa, migrates hundreds of kilometres between summer maternity caves and winter hibernation caves because different microclimatic conditions are required for these purposes (Herselman 1978 in McDonald *et al.* 1990b). In one maternity cave, the roost-site temperature was 21 °C and the relative humidity 85%. Often shares roosts with *Rhinolophus capensis* and *Miniopterus natalensis* (Smithers 1983, as *M. schreibersii*). Does not become torpid during day at 21–24 °C (Happold & Happold 1988) but, in South Africa, hibernates during winter (Laycock 1976, Bernard unpubl.). Predicted mean maximum urine concentration is medium (3686 mOsmol/kg), but captive bats drank regularly each day and are unlikely to be independent of drinking water in the wild except for some periods during the hibernation season (Happold & Happold 1988).

Foraging and Food Very little is known. Has been mist-netted in open spaces close to trees, and probably forages in such places for volant insects. Morphological features predict foraging by gleaning as well as slow-hawking (Fenton & Bogdanowicz 2002). Although sometimes found near open water with *M. bocagii* (M. Happold pers. obs.), and also mist-netted close to surface of running water (Seamark 2005), it possibly comes to water to drink and there is as yet no evidence, from morphology or field observations, that *M. tricolor* trawls for prey or forages over water (cf. *M. bocagii* and *M. capaccinii*). Diet insectivorous: details not known.

Echolocation In South Africa, Taylor (2000) recorded steep angular FM calls beginning around 86 kHz and falling to ca. 33 kHz;

call-duration 3 ms. In Malawi, one individual emitted steep linear FM calls as it was released (Figure 118r); start-frequency 56–101 kHz; end-frequency 43–49 kHz; mean peak-frequency 49 kHz; maximum call-duration 2.25 ms (19 calls; M. Happold pers. comm.). The significance of these differences needs investigating: probably they only reflect differences in the activities and environments of the bats at the time.

Social and Reproductive Behaviour In South Africa, apparently usually roosts huddled together in groups of a few dozen, but has also been observed in colonies of up to 1400 individuals in KwaZulu–Natal midlands (Laycock 1976) and 2000 individuals in Western Cape in summer (Taylor 2000). During winter, groups and colonies include both sexes. In summer, the sexes segregate and ♀♀ roost together, sometimes in very large numbers, in maternity caves while giving birth and lactating (Laycock 1976, Bernard 1982b). The roosting behaviour of ♂♂ during summer is not known: they are rarely seen but one record suggests that they possibly roost singly at this time (Taylor, P. 1998). In KwaZulu–Natal, ♀♀ and volant young leave the maternity colonies in late Jan. Most migrate to winter hibernacula where ♂♂ and ♀♀ reunite and mate prior to hibernating. At this time, most maternity caves are deserted but some are also used as hibernacula.

Reproduction and Population Structure Litter-size: one ($n = 19$). At ca. 29°S (KwaZulu–Natal, South Africa), the reproductive chronology is restricted seasonal monoestry with copulation in autumn (Apr); sperm storage by the ♀ through winter; ovulation and fertilization in Aug–Sep; parturition in Nov–Dec after gestation of ca. 63 days, and lactation for ca. six weeks (Bernard 1982b). Most ♀♀ become sexually mature when 4–5 months old, the remainder a year later (Wingate 1986).

Predators, Parasite and Diseases Predators include Spotted Eagle-owls *Bubo africanus* in Ethiopia (Demeter 1982). Ectoparasites include fleas *Rhinolophopsylla capensis*, *R. ectopa* (Siphonaptera: Ischnopsyllidae); bat-flies *Nycteribia capensis*, *N. latiterna*, *Penicillidia fulvida* (Diptera: Nycteribiidae), *Raymondia hardyi* (Diptera: Streblidae); ticks *Eschatocephalus vespertilionis*, *Ixodes simplex* (Acari: Ixodidae); and seven species of mites (Acari: Spinturnicidae, Macronyssidae, Myobiidae, Trombiculidae, Chirodiscidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

In South Africa, winter hibernation caves and summer maternity caves are limited in availability, and human disturbance of bats in these caves could have a severe impact on populations.

Myotis welwitschii WELWITSCH'S MYOTIS

Fr. Murin de Welwitsch; Ger. Welwitschs Mausohr

Myotis welwitschii (Gray, 1866). Proc. Zool. Soc. Lond. 1866: 211. NE Angola.

Taxonomy Originally *Scotophilus welwitschii*. Synonyms: *venustus*. Subspecies: none. Molecular evidence suggests *M. welwitschii* is closely related to *M. emarginatus* (Ruedi & Mayer 2001). Subsequently, *M. welwitschii* and the Oriental species, *M. formosus*, were found to be sister taxa by Bickham *et al.* (2004) and Stadelmann *et al.* (2004). Chromosome number (South Africa): $2n = 44$; aFN = 50 (Rautenbach *et al.* 1993).

Description Medium-small, very spectacular microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears not funnel-shaped; pelage not frizzled; FA: 52–60 mm; wings and interfemoral membrane with conspicuous pattern of black and orange; ventral hairs bicoloured. Sexes similar. Pelage dense, woolly, without sheen; mid-dorsal hairs 7–8 mm. Dorsal pelage orange; hairs tricoloured, cream with blackish-brown base and orange tip. Ventral

pelage cream slightly suffused with orange; hairs bicoloured, blackish-brown with cream tip. Muzzle naked, orange with black spots. Ears orange with small black spots and black edges; of medium relative length for an African *Myotis* (19–25 mm, 37.8 [32–48]% of FA, $n = 20$); outer margin with no notch. Tragus long, bluntly pointed, ca. half of E. Wings strikingly particoloured – outer arm-wing and hand-wing black with the bones outlined in orange; inner arm-wing orange with small black spots (Figure 149f). Wing-membranes naked; attaching to base of first toe. Tibia naked. Hindfoot relatively short (47.4 [37–56]% of Tib, $n = 14$). Calcar moderately robust, extending at least half-way to tip of tail. Postcalcereal lobe poorly developed or absent. Interfemoral membrane orange with small black spots; ventral surface with sparse backward-pointing hairs; posterior margin with sparse fringe of straight, bristle-like hairs between tips of calcars and tip of tail. Tail fully enclosed by interfemoral membrane or with part of last vertebra projecting beyond membrane.

Skull comparatively large and robust. Braincase comparatively low, profile of forehead region (viewed laterally) moderately concave. Sagittal crest low anteriorly, absent posteriorly. Middle upper premolar reduced (reaching only slightly above cingulum of anterior premolar or lower, and much less than half crown area of anterior premolar); partly to fully displaced lingually, anterior and posterior premolars separated or in contact. Anterior and middle lower incisors with three conspicuous cusps and a fourth, which is low and inconspicuous.

Geographic Variation No subspecies are currently recognized (Kock 1967, Simmons 2005).

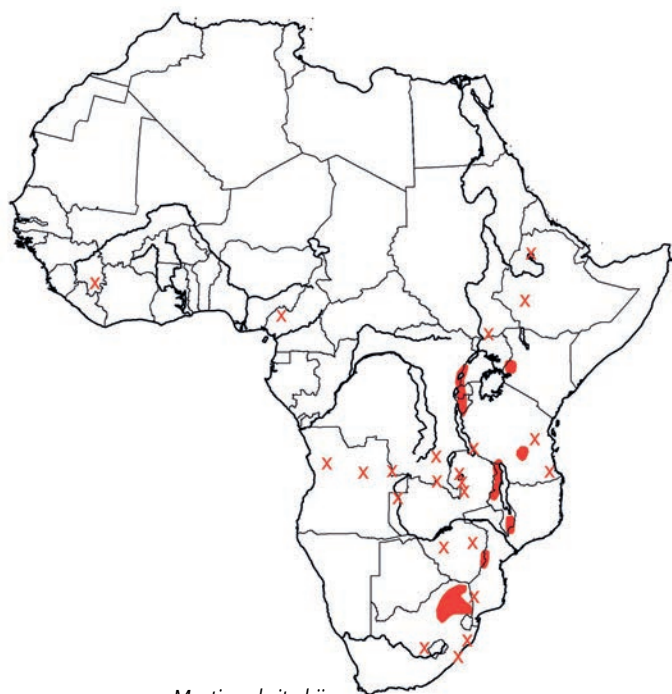

Similar Species Only two other *Myotis* in Africa have wings with a pattern in contrasting colour (Table 29, p. 691):

Myotis tricolor (sometimes). Almost always smaller (FA: 47–53 mm).

Wing colours, if pattern is present, black and dark reddish-brown; pattern inconspicuous. Ventral hairs tricoloured.

M. morrisi. Smaller (FA: 45, 47 mm). Wing colours black and pale yellow or pale orange; pattern moderately conspicuous. Ventral hairs unicoloured.

Distribution Endemic to Africa. Until recently, known only from the Sudan Savanna, Zambezi Woodland, Coastal Forest Mosaic, Highveld and Afromontane–Afroalpine BZs and the Eastern Rainforest–Savanna Mosaic in the eastern half of Africa south of the Sahara, from Ethiopia to E Angola and KwaZulu–Natal, South Africa. Now also known from three specimens from Simandou Range, Guinea (Fahr & Ebigo 2003) and from the Bamenda Highlands, Cameroon (06°05'27 N, 10°18'09 E) (Sedláček *et al.* 2006). This last record bridges the gap of 4400 km between the Simandou Range and the nearest known localities east of the rainforest, mentioned by Fahr & Ebigo (2003), and suggests that the remaining gaps in paramontane savanna areas probably reflect insufficient sampling.

Myotis welwitschii

Habitat Recorded from montane grassland near forest in Guinea, afromontane vegetation (2200 m) in Ethiopia, montane forests (2000–2100 m) in Uganda and Burundi (Stanley *et al.* 1996b), montane forests in Kenya, Tanzania, NE Zambia and N Malawi, wetter and drier miombo woodland and riverine woodland at 1000 m, 500 m and 100 m in Malawi (Happold *et al.* 1987, Happold & Happold 1997), woodland savannas elsewhere in south-central and southern Africa, and coastal forest surrounded by Thornveld in KwaZulu–Natal (Taylor, P. 1998). Koopman (1986) suggested that these bats remain close to mountains although not confined to high altitudes: many subsequent records support this (Fahr & Ebigo 2003) but not all (e.g. Chiromo in the Lower Shire Valley, Malawi).

Abundance Rarely encountered and considered rare throughout its geographic range.

Adaptations Aspect ratio low; wing-loading very low. Flight fast or slow with great manoeuvrability; can take off from ground; cannot hover. Turns usually by banking (minimum radius <25 cm), occasionally by stalling-and-twisting; individuals sustained flight within a 1×1×1 m enclosure for up to five circuits/flight (2 bats, 10 flights each; M. Happold unpubl.). Cursorial locomotion slow and awkward. By day, individuals hang in bushes and trees (Smithers & Wilson 1979, Pienaar *et al.* 1980, Rautenbach 1982) and are well camouflaged by their resemblance to dead leaves. One was found in a furred leaf of a banana plant at Livingstonia, Malawi (Ansell & Dowsett 1988) but no further records of banana leaves as day-roosts were obtained despite almost two years of intensive routine searching in Malawi – including in areas where *M. welwitschii* occurs – associated with studies of the leaf-roosting Banana Pipistrelle *Pipistrellus nanus* (Happold & Happold 1990b, 1996, Bernard *et al.* 1997). In Zimbabwe, some specimens were ‘taken in houses’ (Smithers & Wilson 1979) but Smithers (1983) reports that *M. welwitschii* enters houses at night while foraging, so it seems probable that the captured bats were not roosting in the houses. Stuart & Stuart (1988) state that *M. welwitschii* roosts in hollow trees, but the source of this information is not given and it needs confirmation. Not known to roost in deep caves (*contra* Ratcliffe 2002).

Foraging and Food There is no evidence that these bats forage by trawling over open water (cf. *M. bocagii*), but they have been recorded flying low over streams and a farm dam (e.g. Ansell & Ansell 1973, M. Happold unpubl.) as well as near the ground well away from water. They sometimes fly into houses while foraging. Diet in wild not known: observations in captivity suggest preference for soft-shelled insects, but faecal pellets from one individual contained remains of small beetles (M. Happold unpubl.).

Echolocation Search-phase calls of one individual (tethered) were steep linear FM sweeps; bandwidth 30–90 kHz; end-frequency 9–33 kHz; peak-frequency 35–55 kHz (usually 41–43 kHz. (Figure 118s; M. Happold unpubl.).

Social and Reproductive Behaviour As yet, only found roosting singly (Smithers & Wilson 1979, Pienaar *et al.* 1980), but data are limited.

Reproduction and Population Structure No information.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.
Widespread.

Subfamily MINIOPTERINAE – Long-fingered Bats

Miniopterinae Dobson, 1875. Ann. Mag. Nat. Hist., ser. 4, 16: 349

Diagnostic combination of characters: second phalanx of third finger ca. three times longer than the first; ears not funnel-shaped, tragus short and blunt; braincase high and rounded; five upper cheekteeth; no baculum. The third finger has a characteristically bent appearance because the first phalanx is angled anteriorly towards the line of the second finger (Figure 117c), and *Miniopterus* are sometimes called ‘bent-winged’ bats. Pelage thick, short and velvety. Dental formula

$2^{123}/_{3133} = 36$. Some other external characters and craniodental characters of African *Miniopterus* are shown in Figure 152.

This subfamily contains only one genus, *Miniopterus*. Based on the presence of a vestigial anterior upper premolar in *Miniopterus schreibersii*, the absence of a baculum and the relative elongation of the second phalanx of the third finger, Mein & Tupinier (1977) proposed that this subfamily should be raised to family status. This is supported

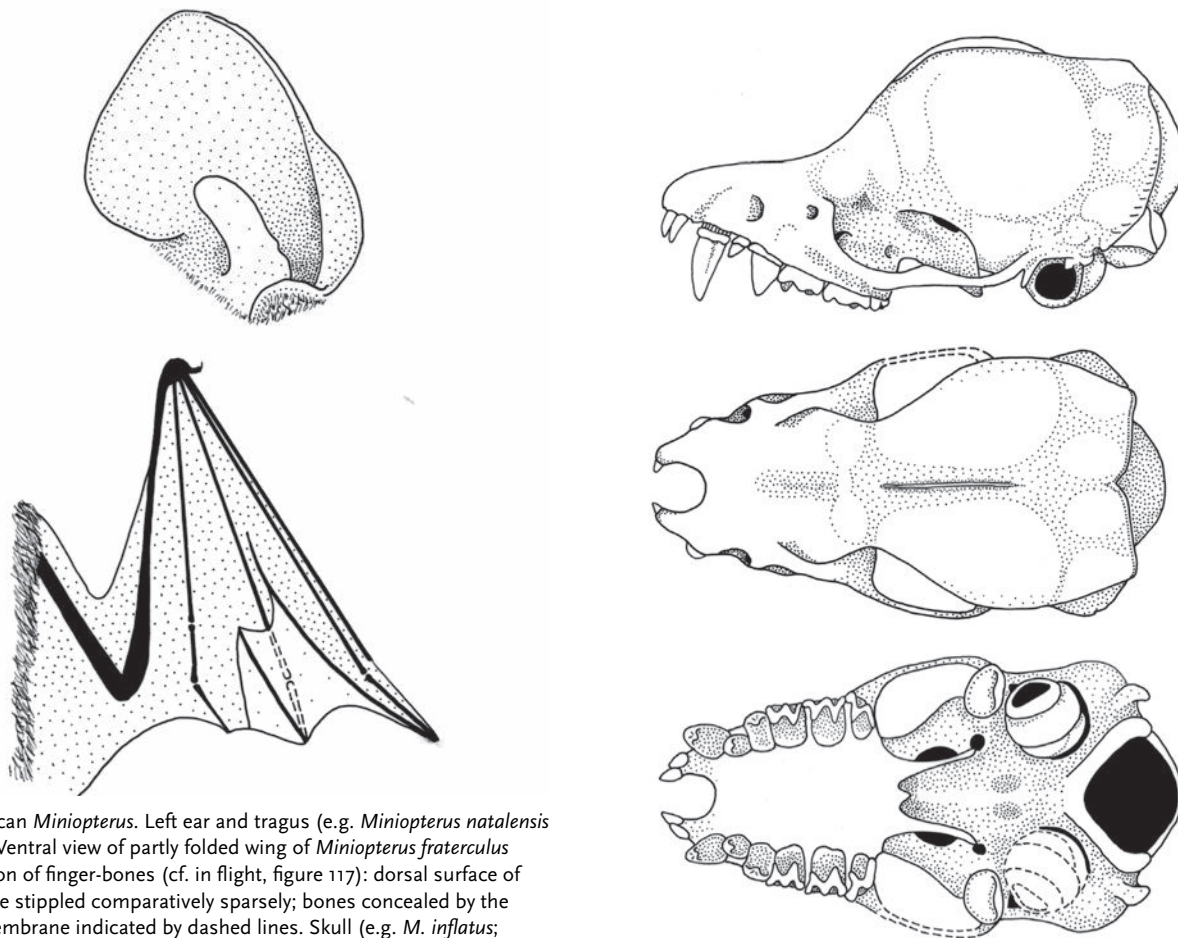

Figure 152. African *Miniopterus*. Left ear and tragus (e.g. *Miniopterus natalensis* from Malawi). Ventral view of partly folded wing of *Miniopterus fraterculus* showing position of finger-bones (cf. in flight, figure 117): dorsal surface of wing-membrane stippled comparatively sparsely; bones concealed by the folded wing-membrane indicated by dashed lines. Skull (e.g. *M. inflatus*; holotype, BMNH 3.2.4.8).

by the molecular evidence of Hofer & Van Den Bussche (2003), who indicate that this taxon represents an extremely divergent lineage relative to other vespertilionids and, in some analyses, is sister to the Molossidae and the New World family Natalidae. Pending further evidence, subfamilial status is retained here, following Simmons

(2005). However, since this profile was submitted, familial status has been confirmed by Miller-Butterworth *et al.* (2007).

Meredith Happold

GENUS *Miniopterus* Long-fingered Bats

Miniopterus Bonaparte, 1837. Fauna Ital. 1, fasc. 20. Type species: *Vespertilio ursinii* Bonaparte, 1837 [= *Vespertilio schreibersii* Kuhl, 1817].

Miniopterus schreibersii.

A polytypic genus with 19 species recognized by Simmons (2005), of which six occur in Africa, three in Madagascar (with one of these also in Comores), and the remainder collectively ranging from S Eurasia to Japan and through the Indo-Australian archipelago to New Caledonia, Vanuatu (New Hebrides) and Australia. One of the six African species recognized by Simmons (2005) is considered here to be a subspecies but its specific status has now been confirmed (see profile of *M. inflatus*). Also, since these profiles were submitted, based on levels of genetic variation, Juste *et al.* (2007) showed that a distinct, as yet undescribed species occurs in Zambia (FA: 44–45 mm, n = 2): not profiled or mapped. For diagnostic characters of *Miniopterus*, see subfamily Miniopterinae.

Members of this genus are cave-roosting bats, which are well adapted for cursorial locomotion: they can scuttle and climb with greater competence and speed than other African vespertilionids. Like emballonurids and molossids, which are very competent scuttlers and climbers, *Miniopterus* can 'furl' their wing-membranes. They do this by folding the very long second phalanx of the third finger, and the long second phalanx of the fourth finger, ventrally against the short first phalanges and metacarpals (Figure 152), and this enables the legs to move fairly freely. These bats have medium to very high aspect ratios and low to medium wing-loadings, and can fly slowly or rapidly with great manoeuvrability, and can therefore forage in both open and moderately cluttered places. At least some species are migratory, and

some hibernate. They roost mostly in small to very large groups, but little is known about their social behaviour and mating systems, except for *M. minor*, which appears to have a mating system based on lekking. All African species for which data are available are monogamous and seasonally monoestrous. Delayed implantation is exemplified by the species in temperate habitats, and intra-specific geographical differences in the timing of reproductive events have been documented for *M. natalensis*. *Miniopterus natalensis* is also capable of facultative retarded embryonic development. The reproductive biology of *M. minor* is particularly interesting because ♀♀ have a 'silent heat', which might trigger the lekking behaviour of the ♂♂.

All members of this genus show a remarkable degree of morphological uniformity, and this has made classification of the different forms difficult and controversial (e.g. Harrison 1953, Corbet & Hill 1992, Peterson *et al.* 1995). Juste & Ibáñez (1992) and Koopman (1993, 1994) recognize four species in Africa (*fraterculus*, *inflatus*, *minor* and *schreibersii*). Simmons (2005), following Peterson *et al.* (1995), recognizes *africanus* as distinct from *inflatus*, and *natalensis* as distinct from *schreibersii*. Here, *africanus* is treated as a subspecies of *M. inflatus* because, when these profiles were written, pelage colouration appeared to be the main difference between these forms and this might have reflected nothing more than a darkening of pelage associated with more humid habitats. The value of colour as a diagnostic character is also potentially unreliable because older pelage of one colour might be replaced by blacker pelage after moulting (as it is in *M. minor*). The separation of *M. natalensis* from *M. schreibersii* is supported by multivariate statistics (Peterson *et al.* 1995) and by differences in the DNA of *M. natalensis* from South Africa and that of *M. schreibersii* from Europe (Miller-Butterworth *et al.* 2005), and these taxa are treated as distinct here. Therefore, tentatively, five species are recognized here, but there is clearly a need for further investigation.

The relationship of several other forms to these five species is also very controversial. Of particular interest are the forms *vicinior*, *dasythrix*, *smitianus* and *villiersi*. Simmons (2005) considers *vicinior* to be a synonym of *M. natalensis*, but the discriminant function of Stoffberg *et al.* (2004), which distinguishes *M. natalensis* from *M. fraterculus* in southern Africa, also distinguishes *vicinior* from *M. natalensis* (M. Happold pers. obs.), suggesting *vicinior* is more likely to be a synonym of *M. fraterculus* (but this needs confirmation). The form *villiersi* (distributed from Guinea to DR Congo) is usually considered a synonym of *M. schreibersii* although it is isolated by the vast Sahara from populations of *M. s. schreibersii* in North Africa and Europe. In contrast, the forms *dasythrix* from Malawi to South Africa (Koopman 1994) and *smitianus* from Ethiopia to Namibia (Koopman 1994) have been placed in both *M. schreibersii* and *M. natalensis*. Peterson *et al.*

(1995) and Simmons (2005) place both forms in *M. schreibersii*, and this treatment is tentatively followed here. This, however, implies that three very similar species, *M. schreibersii*, *M. fraterculus* and *M. natalensis*, occur sympatrically in South Africa and this seems unlikely for ecological reasons. Furthermore, 305 *Miniopterus* from 13 colonies in South Africa, which were identified by DNA sequencing, contained only *M. fraterculus* and *M. natalensis*, both of which differ genetically from *M. schreibersii* from Europe (Miller-Butterworth *et al.* 2005). Unfortunately, it has not yet been possible to determine the DNA characteristics of the type specimens of *dasythrix* and *smitianus*, or any other of these controversial forms.

Because of the remarkable degree of morphological conformity in this genus, distinguishing the five African species is difficult and material should be sent to museum experts, or to laboratories

where molecular techniques are used, to confirm identification. Some species, however, can be distinguished from each other by the measurements given in Table 30 and, at least in southern Africa and Malawi, *M. fraterculus* and *M. natalensis* can be distinguished on the basis of the following discriminant function in which $x > 0$ (positive) indicates *M. fraterculus* and $x < 0$ (negative) indicates *M. natalensis* (Stoffberg *et al.* 2004):

$$x = (\text{HF} \times 0.279417) - (\text{TL} \times 0.989306) + 100$$

All measurements in mm. Abbreviations:

HF = length of hindfoot including claws.

TL = total length of the bat.

Meredith Happold

Miniopterus fraterculus LESSER LONG-FINGERED BAT

Fr. Minioptère d'Afrique australe; Ger. Kleine Langflügelfledermaus

Miniopterus fraterculus Thomas and Schwann, 1906. Proc. Zool. Soc. Lond. 1906: 162. Knysna, Western Cape Province, South Africa.

Taxonomy Synonyms: uncertain – pending further evidence, *vicinior* is considered here to be a synonym of *fraterculus* because, in the discriminant function of Stoffberg *et al.* (2004), x is positive, as in *fraterculus*. In contrast, Simmons (2005) considers *vicinior* a synonym of *M. natalensis*. Subspecies: pending revision, none recognized here. Koopman (1966) considered *fraterculus* to be a subspecies of *M. minor* but, later, *fraterculus* was again considered distinct (e.g. Hayman & Hill 1971, Meester *et al.* 1986, Koopman 1993, 1994, Peterson *et al.* 1995). Chromosome number (South Africa): $2n = 46$; $aFN = 50$; not karyologically distinct from *M. schreibersii* in South Africa (Rautenbach *et al.* 1993). In contrast, considered genetically distinct from *M. schreibersii* in South Africa by Miller-Butterworth (2001). The identities of the bats referred to as *M. schreibersii* in these last two studies have not been confirmed but they most probably represent *M. natalensis* (see Genus *Miniopterus*).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; bent-winged; five upper and six lower cheekteeth on each side; medium-sized

for African *Miniopterus*, FA: 43.3 ± 1.1 mm; TL: 97.6 ± 3.5 mm; in the discriminant function of Stoffberg *et al.* (2004) (see Genus *Miniopterus*) x is positive (cf. negative in *M. natalensis*). Sexes similar. Pelage very soft, dense, velvety; mid-dorsal hairs ca. 9 mm; crown and forehead with thick, erect, velvety pelage concealing most of posterior surface of ears and dorsal surface of muzzle. Dorsal pelage (grey-phase) very dark brown (perhaps sometimes greyish-black) in southern Africa, or greyish-brown (Kenya); hairs unicoloured or with darker base. Holotype very dark brown. A rich reddish-brown orange-phase is known at some localities. Ventral pelage same as dorsal pelage or slightly paler. Head high-domed. Muzzle narrow; nostrils very small. Ears dark grey or blackish-brown, relatively short ($22.6 [18–30]\%$ of FA), roughly triangular, tip rounded. Tragus ca. half of E, but very variable in preserved material; narrow, basal two-thirds parallel-sided, posterior margin becoming convex near tip; tip rounded. Wings moderately long and narrow, very dark grey, dark brown or black; second phalanx of third finger ca. three times longer than the first; first phalanx of third finger angled forward so third finger appears bent. Interfemoral membrane large, very dark

grey or black; calcars stout. In Malawi and South Africa (at least), TL comparatively short (mean \pm 1 S.D: 97.6 ± 3.5 mm) and hindfeet comparatively long (8.9 ± 0.9 mm) (cf. *M. natalensis*).

Skull small for an African *Miniopterus*. Profile of forehead region (viewed laterally) very strongly concave; braincase elevated (as in all *Miniopterus*).

Geographic Variation Uncertain. Pending revision, no subspecies are recognized here.

Similar Species African *Miniopterus* are very difficult to distinguish (Table 30, p. 712):

Miniopterus minor. Forearm usually shorter (39.8 ± 1.0 [37–42] mm).

Skull sometimes smaller (GLS: 13.6 [11.1–14.5] mm).

M. natalensis. In the discriminant function of Stoffberg *et al.* (2004) (see Genus *Miniopterus*), x is negative.

M. schreibersii. On average, larger (FA: 45.9 [44–49] mm; GLS: 15.8 [14.9–16.5] mm).

M. inflatus. Forearm almost always longer (48.3 [45–52] mm). Skull longer (GLS: 16.9 [16.0–17.8] mm).

Distribution In Africa, traditionally considered to occur mainly in the Zambezian Woodland, Coastal Forest Mosaic, Afromontane–Afroalpine and South–West Cape BZs in Zambia, Malawi, S Mozambique, E Zimbabwe, South Africa and perhaps Angola. The identities of specimens from Malawi and South Africa have been confirmed by the discriminant function of Stoffberg *et al.* (2004). In addition, the form *vicinior* (see Taxonomy) occurs in the Rainforest BZ and Rainforest–Savanna Mosaic in NE DR Congo. According to Peterson *et al.* (1995), *M. fraterculus* also occurs in Nigeria, Cameroon, Kenya and Tanzania. Specimens identified by the discriminant function of Stoffberg *et al.* (2004) have been found in the Somalia–Masai and Zambezian Woodland BZs of Kenya and Tanzania. However, specimens from Cameroon and

Nigeria probably represent the form *villiersi*, which is treated here as a synonym of *M. schreibersii*. Because *M. fraterculus*, *M. natalensis* and *M. schreibersii* are difficult to distinguish, some records in the literature are probably erroneous. Extraliminally: Madagascar (Peterson *et al.* 1995).

Habitat In Malawi, recorded from montane evergreen forest, remnant lowland rainforest and wetter miombo woodland near forests of some kind, at 900–1680 m (Happold & Happold 1997). In South Africa, recorded from the coastal belt (rarely more than 300 km inland) in a variety of habitats including drier savanna bushveld to moister mistbelt, afromontane and coastal forests, where suitable day-roosts are present (Taylor, P. 1998, 2000). Absence from the interior suggests distribution is limited by rainfall. In KwaZulu–Natal, South Africa, most localities seem associated with major river valleys.

Abundance Uncertain. Uncommonly recorded throughout geographic range. In South Africa, apparently much less common than *M. natalensis* (Taylor 2000).

Adaptations Aspect ratio high; wing-loading low; wing-tip roughly triangular (M. Happold unpubl.). Flight fast to slow with great manoeuvrability; wing-beats shallow and irregular; frequently glides downwards at great speed. Can take off from ground; not known to hover. Turns by banking (minimum radius of turn <25 cm) or by stalling-and-twisting; individuals sustained flight in a $1 \times 1 \times 1$ m enclosure for up to four circuits/flight (6 bats, 10 flights each, M. Happold unpubl.). Can scuttle and climb competently and rapidly. By day, roosts in caves, rock fissures and overhangs, disused mine-adits and tunnels; clings in contact to walls, ceilings or other bats (Lang & Chapin 1917b, Smithers 1983, Taylor 2000). Often shares day-roosts with *M. natalensis*. Migrates between summer- and winter-roosts, and makes short-distance, inter-cave movements in winter (Bernard 1980b). Becomes torpid during day at 21 – 24 °C (Happold & Happold 1988). Hibernates in winter in South Africa but loses only 15% of body mass during first half of winter, suggesting that individuals periodically become active and feed during this period (cf. *M. natalensis*) (Bernard 1980b).

Foraging and Food Foraging: no information but, on basis of wing morphology, likely to be similar to *M. natalensis*. Bats (identified as *M. cf. fraterculus*) in Zimbabwe apparently ate mainly aquatic Diptera, but also took some Lepidoptera and Coleoptera (Fenton *et al.* 1977).

Echolocation Search-phase calls of seven Malawian individuals included steep FM/QCF calls with start-frequencies as high as 104 kHz, end-frequencies 50–56 kHz (usually 50–54 kHz), and maximum duration 3.5 ms, and also smooth steep/shallow FM sweeps with similar end-frequencies and maximum duration ca. 6 ms (Figure 118q; M. Happold unpubl.). In South Africa, search-phase calls have end-frequency 54.4 (44–57) kHz; peak-frequency 62.3 (59.8–65.8) kHz; call-duration 3.7 (2.6–4.5) ms (10 bats, Miller-Butterworth *et al.* 2005).

Social and Reproductive Behaviour In southern Africa, roosts in tightly packed groups of usually less than 100 individuals. Females congregate in maternity roosts to give birth and lactate. Hibernacula are occupied by both sexes (R. T. F. Bernard unpubl.).

Miniopterus fraterculus

Reproduction and Population Structure Litter-size: one. At 29–31° S (midlands of KwaZulu–Natal, South Africa), reproductive chronology is restricted seasonal monoestry with copulation, ovulation and fertilization in May and Jun, delayed implantation for ca. 2.5 months during winter, active foetal growth for ca. 4 months and parturition in Nov–Dec after gestation of 5.5–6 months (Bernard 1980b). The period of delayed implantation is 1.5–2 months shorter than in *M. natalensis* at the same locality, suggesting that *M. fraterculus* has had a shorter history at southern latitudes (Bernard 1980b). The right horn of the uterus is larger than the left and, in one study, 94% of ovulations originated in the left ovary and all implantations in the right horn (Bernard 1980c).

Predators, Parasites and Diseases Ectoparasites include a bat-fly (Diptera) (*M. Happold* unpubl.) and mites *Leptotrombidium lawrencei* (Acari: Trombiculidae) and *Macronyssus granulosus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984; host given as subspecies of *M. minor*).

Conservation IUCN Category: Least Concern.

Miniopterus inflatus GREATER LONG-FINGERED BAT

Fr. Grand minioptère africain; Ger. Aufgeblasene Langflügelfledermaus

Miniopterus inflatus Thomas, 1903. Ann. Mag. Nat. Hist., ser. 7, 12: 634. Efulen, Cameroon.

Taxonomy Synonyms following Koopman (1993): *africanus*, *rufus*. Juste & Ibáñez (1992) and Koopman (1993, 1994) included *africanus* and *rufus* in *M. inflatus*. In contrast, based on multivariate statistics, Peterson *et al.* (1995) considered *africanus* to be a distinct species (but without giving diagnostic characters) and they considered *rufus* to be a subspecies of *M. inflatus*. In Kenya, where *africanus* and *inflatus* have been found at localities ca. 75 km apart, *africanus* occurs in more arid habitats than *M. inflatus*, it is a grey form whereas *M. inflatus* is reddish-black, and there are subtle differences in the dorsal profile of its skull (viewed laterally) (J. Eger pers. comm.). Although these differences suggest that *africanus* is distinct, when this profile was written this possibility had not been confirmed by published evidence from other sources (e.g. chromosomes, genetics, echolocation). Furthermore, variation within *africanus* and *inflatus* had not been assessed, and it seemed plausible that the differences in colour reflected only the tendency for colours to be paler in drier habitats than they are in more humid habitats. However, since this profile was written, the specific status of *africanus* Sanborn, 1936 has been confirmed by Juste *et al.* (2007), but it was too late to profile *africanus* as a distinct species here. The form *rufus* is treated here as a synonym of *M. inflatus* although it might be a valid subspecies of *M. inflatus*. Because *M. inflatus* has been confused with *M. schreibersii* (especially with *M. s. villiersi*), references to *M. inflatus* in literature and museum records do not always pertain to this species. Data in this profile are, unless stated otherwise, from specimens identified as *M. inflatus* or *M. africanus* by R. Peterson, J. Eger (ROM), or from studies or collections that mention or include specimens having FA

>48 mm and/or GLS >16.5 mm. Chromosome number (Somalia): 2n = 46; aFN = 50. X = medium-sized metacentric; Y = small acrocentric (Ruedas *et al.* 1990).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; bent-winged; five upper and six lower cheekteeth on each side; the largest African *Miniopterus* (FA: 48.3 ± 1.3 mm; TL: 111.2 ± 7.6 mm). Sexes similar. Pelage dense, silky; mid-dorsal hairs 5–7 mm. Dorsal pelage variable (see Geographic Variation), ranging from almost black with a reddish tint, through medium reddish-brown, sepia brown to greyish-brown; hairs unicoloured or with paler tip. Ventral pelage slightly to distinctly paler than dorsal pelage; hairs unicoloured or with paler tip. Head with high-domed forehead; muzzle fairly short and narrow. Ears relatively short (22.6 [18–30]% of FA), subtriangular; tip bluntly rounded. Tragus with anterior and posterior margins straight and parallel; tip rounded; ca. half of E (but very variable in preserved material). Wings long, narrow, greyish-brown, dark brown or almost black; second phalanx of third finger ca. three times longer than the first; first phalanx of third finger angled forward so third finger appears bent. Interfemoral membrane same colour as wings; anterior quarter to half of dorsal surface with downy hairs and sometimes with downy hairs extending further posteriorly close to tail.

Skull large for an African *Miniopterus*. Profile of forehead region (viewed laterally) very strongly concave; braincase elevated but varying in degree; sagittal crest present but varying in prominence (see Geographic Variation).

Geographic Variation Currently, the status of taxa that include the largest of the African *Miniopterus* is uncertain (see Taxonomy). The most distinctly different forms, tentatively treated here as subspecies, are:

M. i. africanus. Dorsal pelage greyish-brown with paler sheen; hairs greyish-brown with paler tip. Ventral pelage paler than dorsal pelage; hairs with more distinctly paler tip. Flight-membranes greyish-brown. Skull with braincase less elevated and less bulbous; muzzle area smaller; sagittal crest low (J. Eger pers. comm.). FA: 48.5 (45–52) mm; Tib: 20.5 (19–23) mm; GLS: 16.8 (16.0–17.4) mm; GWS: 9.2 (8.7–9.6) mm; C–M³: 6.4 (6.0–6.7) mm; n = 47 (Peterson *et al.* 1995).

M. i. inflatus (including *rufus*). Dorsal pelage ranging from very dark brown (holotype), very dark blackish-brown tinged with red (*rufus*), through reddish-brown, sepia brown to greyish-brown; hairs uncoloured or with slightly paler tip. Ventral pelage slightly paler. Flight-membranes dark brown to blackish-brown. Skull with braincase more highly elevated and more bulbous; muzzle area larger; sagittal crest prominent (J. Eger pers. comm.). FA: 48.2 (44–51) mm; Tib: 18.9 (18–21) mm; GLS: 17.0 (16.4–17.8) mm; GWS: 9.3 (8.9–9.8) mm; C–M³: 6.5 (6.3–6.9) mm; n = 162 (from Peterson *et al.* 1995).

Similar Species African *Miniopterus* are very difficult to distinguish (Table 30, p. 712):

Miniopterus minor. Smaller and lighter (FA: 39.8 [37–42] mm; GLS: 13.6 [11.1–14.5] mm; WT: 6 [3–9] g).

M. fraterculus. Forearm almost always shorter (43.3 [41–45] mm). Skull shorter (GLS: 14.4 [13.3–15.5] mm).

M. natalensis. Forearm almost always shorter (44.8 [43–46] mm). Skull shorter (GLS: 14.3 [13.6–14.9] mm).

M. schreibersii. On average, FA shorter (45.9 [44–49] mm). Skull

almost always smaller (GLS: 15.8 [14.9–16.5] mm; C–M³: 5.9 [5.4–6.3] mm).

Distribution Endemic to Africa. Recorded from widespread but mostly isolated localities south of the Sahara, in the Rainforest BZ, the Rainforest–Savanna Mosaics, the Somalia–Masai Bushland, Zambezian Woodland, Coastal Forest Mosaic and Afromontane–Afroalpine BZs. According to Peterson *et al.* (1995) and/or J. Eger (pers. comm.), *M. i. africanus* occurs in Eritrea, Ethiopia, Kenya, Tanzania, Botswana and Namibia, and *M. i. inflatus* occurs in Liberia, possibly Nigeria, Cameroon, Equatorial Guinea, Gabon, Central African Republic, DR Congo, Uganda, Burundi, Kenya and Mozambique (with specimens from DR Congo, Uganda, Burundi and Kenya representing the form *rufus*). *Miniopterus inflatus* has also been recorded recently from ca. 15° 57' S, 35° 29' E (Likabula Mission, Malawi) by Miller-Butterworth *et al.* (2005) and at 08° 08' N, 08° 34' W (Mt Béro, Guinea) by Fahr *et al.* (2006) (both not mapped).

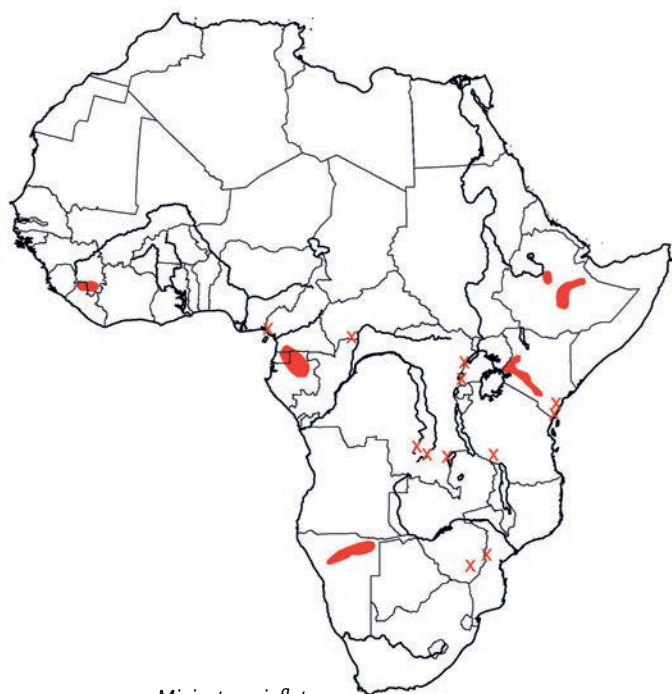

Habitat In Kenya, *M. i. africanus* occurs in the Rift Valley and comparatively dry savanna habitats. In Ethiopia, it has been recorded from open thorn scrub and grassland with scattered acacias, semi-desert grassland with areas of *Acacia* scrub and volcanic caves, and a gorge with *Acacia* and broadleaved scrub and limestone caves (Hill & Morris 1971, Largen *et al.* 1974). Other Ethiopian localities appear to be located in altimontane and afromontane vegetations (terminology: White 1983). In Kenya, *M. i. inflatus* occurs in comparatively moist forests associated with highlands. Elsewhere, it is recorded from lowland rainforest, caves in the rainforest zone and from caves in afromontane vegetation and drier miombo woodland. The presence of caves or mines seems essential.

Abundance Uncertain. Rare or uncommon in collections; probably uncommon throughout geographic range although large numbers sometimes become concentrated in a few maternity caves during the parturition season (see below).

Adaptations Aspect ratio high; wing-loading medium, wing-tips rounded (Norberg & Raynor 1987). Therefore this bat predictably flies fast or moderately slowly with great manoeuvrability (as does *M. fraterculus*). By day, roosts in caves (including volcanic and limestone caves, and those formed by granite boulders) and mine-adits. Individuals often tuck themselves into cracks and fissures, but sometimes hang from ceilings. Sometimes roosts with *Hipposideros caffer* and *H. gigas* in Gabon (Brosset 1969), *H. ruber* in Liberia (Wolton *et al.* 1982) and with *Miniopterus natalensis* in southern Africa (Smithers 1983, as *M. schreibersii*).

Foraging and Food Based on wing morphology, predictably forages for flying insects by moderately fast-hawking in open, uncluttered places including clearings, above trees and over water. One individual was observed flying high (6–8 m) among widely spaced *Acacia* trees in open scrub and grassland (Hill & Morris 1971). Jones (1971) caught ten flying under a bridge over a stream in lowland rainforest in Equatorial Guinea (as *M. schreibersii*).

Echolocation No information.

Miniopterus inflatus

Social and Reproductive Behaviour Sometimes roosts singly, sometimes in small groups (e.g. a group of eight immature ♀♀ was recorded at Mt Nimba, Liberia by Wolton *et al.* 1982). In NE Gabon, ♀♀ congregate to give birth and raise young in a maternity cave estimated to house ca. 40,000 individuals at this time (Brosset 1969). At other times, the numbers of *M. inflatus* in other caves in the area fluctuates from day to day, suggesting that individuals utilize many different caves and frequently move from cave to cave. The occurrence of *M. inflatus* in these Gabonese caves has been confirmed (M. Happold unpubl.).

Reproduction and Population Structure Litter-size: one (n = 3). At ca. 00° 40' N (NE Gabon), the reproductive chronology is restricted seasonal monoestry with copulation in Jul, births in Oct and lactation ending prior to Jan (Brosset 1969, Brosset & Saint Girons 1980). In Zimbabwe, three ♀♀, each with one embryo in the right uterine horn, were taken in Oct (Smithers & Wilson 1979).

Predators, Parasites and Diseases Ectoparasites include bat-flies *Nycteribia schmidli* and *Penicillidia allisoni* (Diptera: Nycteribiidae) (Wolton *et al.* 1982). A list of ectoparasites is given by Anciaux de Faveaux (1984) but the identities of the hosts have not been confirmed.

Conservation IUCN Category (including *africanus*): Least Concern.

Miniopterus minor LEAST LONG-FINGERED BAT

Fr. Petit minioptère africain; Ger. Zwerg-Langflügelfledermaus

Miniopterus minor Peters, 1867. Monatsber. K. Preuss. Akad. Wiss. Berlin 1866: 885 [publ. 1987]. Coast opposite Zanzibar I., Tanzania.

Taxonomy Synonyms: *newtoni*, *occidentalis*. Subspecies: three of uncertain status. Considered conspecific with *M. fraterculus* (Aellen & Brosset 1968) but later considered to be a distinct species on basis of differences in cranial proportions. For taxonomic review see Juste & Ibáñez (1992). Formerly included *manavi* and *griveaudi* of Madagascar and Comoro Is., but Peterson *et al.* (1995) considers these to be distinct species. See also Juste *et al.* (2007), who consider *newtoni* to be a valid species. Chromosome number: not known.

Description Small to very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; bent-winged; five upper and six lower cheekteeth on each side; the smallest African *Miniopterus* (FA: 39.8 ± 1.0 mm; TL: 91.3 ± 3.0 mm); downy pelage on flight-membranes. Sexes similar. Pelage dense, velvety. Dorsal pelage very dark blackish-brown to almost black with slight greyish sheen; hairs dark blackish-brown (almost black) with slightly paler tip. Ventral pelage slightly paler and greyer. Head with high-domed forehead; muzzle short, narrow, with very small nostrils. Ears relatively short (23 [15–27]% of FA), subtriangular, partly concealed by pelage. Tragus moderately long (49.4 [30–70]% of E) with rounded tip. Wings long, narrow, dark brown; dorsal surface with sparse downy hairs; second phalanx of third finger ca. three times longer than the first; first phalanx of third finger angled forward so third finger appears bent. Dorsal surface of anterior half of interfemoral membrane with sparse, downy hairs, visible under microscope. Skull small for an African *Miniopterus*.

Measurements

Miniopterus inflatus and *M. africanus*

FA: 48.3 (45–52) mm, n = 295

Key Reference Brosset 1969.

Meredith Happold

Profile of forehead region (viewed laterally) very strongly concave; braincase elevated (as in all *Miniopterus*).

Geographic Variation Three subspecies are currently recognized but their status is uncertain. For some parameters, mean \pm S.D.

M. m. minor: Kenya and Tanzania. FA: 39.8 ± 0.65 mm; condylobasal length (CbL): 13.6 ± 0.22 mm.

M. m. occidentalis: lower reaches of Congo R. in Congo and DR Congo. FA: 38.2 ± 0.74 mm, CbL 13.1 ± 0.16 mm.

M. m. newtoni: extraliminally São Tomé. FA: 39.0 ± 0.66 ; CbL 13.3 ± 0.25 mm.

For other measurements see Juste & Ibáñez (1992). Considering the vast distance between the geographic ranges of the African subspecies, and the morphological uniformity of this genus, *minor* and *occidentalis* might be distinct species despite their similar morphological characters. *Miniopterus m. occidentalis* shows greater affinity with *M. m. newtoni* than with *M. m. minor* (Juste & Ibáñez 1992).

Similar Species African *Miniopterus* are very difficult to distinguish (Table 30, p. 712):

Miniopterus fraterculus. Forearm usually longer (43.3 ± 1.1 [41–45] mm). Skull sometimes larger (GLS: 14.4 [13.3–15.5] mm).

Miniopterus minor

M. natalensis. Forearm longer (44.8 [43–46] mm). Skull sometimes larger (GLS: 14.3 [13.6–14.9] mm; C–M³: 5.7 [5.5–6.0] mm).

M. schreibersii. Forearm longer (45.9 [44–49] mm). Skull almost always larger in some dimensions (GLS: 15.8 [14.9–16.5] mm; C–M³: 5.9 [5.4–6.3] mm).

M. inflatus. Larger and heavier (FA: 48.3 [45–52] mm; GLS: 16.9 [16.4–17.8] mm; WT: 13 [8–19] g).

Distribution Endemic to Africa. In Africa, there is a western population in the Southern Rainforest–Savanna Mosaic around the lower reaches of the Congo R. in Congo and DR Congo (apparently not reaching the coast), and an eastern population in the Coastal Forest Mosaic BZ on the Kenya–Tanzania coast.

Habitat All western records are near caves in woodland savanna habitats (Juste & Ibáñez 1992). The eastern population seems restricted to the coastal savanna and coastal forest mosaic, near caves: it has been recorded in one coastal forest but presumably exploits both forest and savanna components of the mosaic. For bat assemblages associated with *M. minor* in East Africa, see Cockle *et al.* (1998).

Abundance Uncertain. Rare in collections; the rarest African *Miniopterus*.

Adaptations By day, roosts in caves, including those in up-raised coral reefs along the Kenyan coast where *M. minor* was studied by McWilliam (1982, 1988c, 1990). Here, there is a short wet season in Nov–Dec followed by a short warm dry season, and a long wet season from late Mar to late Jun followed by a long cool dry season (McWilliam 1988c). Body weight fluctuates seasonally, with fat being deposited during each of the wet seasons; in ♂♂, weight peaks in Apr–May and again in Dec. During the cool dry season, when food is scarcest and body weight lowest, the bats become torpid during the day. McWilliam (1988c) suggests that this reversible hypothermia

evolved in the tropics as a response to colder dry seasons with concomitant food shortages, and that torpor, together with delayed implantation during these periods, pre-adapted *Miniopterus* for colonization of higher latitudes where winters are even more severe and hibernation occurs. Adults moult during Apr–May in conjunction with the improvement of body condition at the beginning of the long wet season: old browner pelage is replaced by blacker pelage.

Foraging and Food No details available. Like other *Miniopterus*, *M. minor* feeds on insects and predictably forages by moderately fast-hawking or slow-hawking.

Echolocation No information.

Social and Reproductive Behaviour The mating system of *M. minor* living in a cave near the Kenyan coast appears to be based on lekking (McWilliam 1990). During a three-year study, ♂♂ were found in this cave throughout the year, although numbers were usually <10 during the short dry season (Jan, Feb). At the start of the long rains (Apr), the cave population increased markedly as adults (accompanied by weaned young) returned from inland maternity colonies. In ♂♂, sexual regeneration and a marked increase in weight occurred during this wet season. In May, during the cool dry season, adult ♂♂ began to occupy the mating site – an erosion hollow situated in the outer coolest cave-chamber. This site was strategic in that the movements of bats, into or out of the cave, could be monitored from it. Adult ♂♂ competed for places in this site, suggesting that it functioned as a lek, but no copulations were seen and therefore it is possible (albeit unlikely) that mating was random. Successful occupants of the mating site were heavier than others and, having occupied this site during one year, they were more likely to gain access to it in subsequent years. These ♂♂, ca. 30 in number, continued to roost at this site throughout the entire mating season, and ca. 60% of them occupied it for at least two consecutive mating seasons. They produced a pungent odour associated with their urine, and their pelage became damp; possibly an odour plume was created enabling ♀♀ to orientate towards the mating site. Copulation occurred from late Jun to late Jul (see below), and a substantial loss in body weight of ♂♂ (16%) was coincident with their competitive mating activities. The mating site was abandoned at the conclusion of the mating season. Subsequently, colony size increased to a peak of ca. 200 as more adult ♀♀ arrived until, in Oct, ca. 80% of the bats were pregnant ♀♀. Then, in Oct–Nov, most of these ♀♀ migrated inland to maternity caves where, during the main food peak associated with the short inland wet season, they gave birth and suckled their young. The few bats (ca. ten) that remained in the coastal cave were mainly adult ♂♂. Although it not yet certain that *M. minor* exemplifies a mating system based on lekking, there is no evidence of harem-formation or the participation by ♂♂ in parental care.

Reproduction and Population Structure Litter-size: no published information but presumably one. At 04° 10'S (coastal Kenya), the reproductive chronology is restricted seasonal monoestry with reproductive events corresponding closely to the rainfall-induced seasonality of that area (see Adaptations) (McWilliam 1988c, 1990). Spermatogenesis occurs from Apr to Jul (mainly during the long wet season when insects are abundant and the ♂♂ are fat). Females have a 'silent heat' (ovulation without fertilization) in May,

with associated odour secretions that might trigger ♂ competition for occupancy of the 'lek' (see above). A second ovulation with copulation and fertilization occurs in late Jul to early Aug. There is probably a period of delayed implantation of up to three weeks with the result that the most energy-demanding stages of pregnancy are shifted to the beginning of the short wet season. Births and lactation occur during the short wet season when insects are maximally abundant. Males do not breed in their first year. Both sexes do not moult until their second year.

Predators, Parasites and Diseases Ectoparasites include bat-flies *Nycteribia schmidli*, *Penicillidia fulvida* (Diptera: Nycteribiidae), *Ascodipteron minor* (Diptera: Streblidae) and mites *Spinturnix semilunaris* (Acari: Spinturnicidae) and *Macronyssus granulatus* (Acari: Macronyssidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Data Deficient.

The status of the subspecies requires re-evaluation. If any are distinct species, they are probably threatened. Caves used by this species should be protected.

Meredith Happold

Miniopterus natalensis NATAL LONG-FINGERED BAT (NATAL CLINGING BAT)

Fr. Miniopière de Natal; Ger. Natal-Langflügel-Fledermaus

Miniopterus natalensis (A. Smith, 1834). S. Afr. Quart. J. 2: 59. Durban, KwaZulu–Natal, South Africa.

Taxonomy Originally *Vespertilio natalensis*. Synonyms: following Koopman (1994), Peterson *et al.* (1995) and Simmons (2005), *arenarius*, *breyeri*, *scotinus*. The status and relationships of *natalensis* and the above three forms (and also *dasythrix* and *smitianus*) are uncertain: revision is much needed. *Miniopterus natalensis* is often considered to be a subspecies of *M. schreibersii* (e.g. Meester *et al.* 1986, Koopman 1993). However, *natalensis* is considered to be a distinct species by Harrison (1953), O'Shea and Vaughan (1980) and Koopman (1994): multivariate statistics supports this conclusion (Peterson *et al.* 1995), and so too does genetic evidence (Miller-Butterworth *et al.* 2005). Following Koopman (1994) and Simmons (2005), *arenarius* is tentatively considered here to be a subspecies of *M. natalensis*, and *breyeri* and *scotinus* are treated as synonyms. Harrison (1953) and Meester *et al.* (1986) include *dasythrix* and *smitianus* as synonyms of *M. natalensis*, but Koopman (1994), Simmons (2005) and J. Eger (pers. comm.) consider these are subspecies of *M. schreibersii* and they are tentatively treated as such here. The geographic ranges of *dasythrix* and *smitianus* overlap with the range of *M. natalensis*, so it is possible that both *M. schreibersii* and *M. natalensis* occur sympatrically in southern Africa. It is also possible that *M. natalensis* and/or *M. schreibersii* include more than one species. The form *vicinior* is sometimes included in *M. natalensis* (e.g. Simmons 2005), but is tentatively considered here as a subspecies of *M. fraterculus*. Chromosome number in southern Africa: 2n = 46; aFN = 50 (Rautenbach *et al.* 1993 as *M. schreibersii*).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; bent-winged; five upper and six lower cheekteeth on each side; medium-sized for African *Miniopterus* (FA: 44.8 ± 0.9 mm; TL: 108 ± 2.5 mm); in the discriminant function of Stoffberg *et al.* (2004) (see Genus *Miniopterus*)

x > 0 (positive). Sexes similar. Pelage very soft, dense, velvety; mid-dorsal hairs 7–9 mm. Dorsal pelage (grey-phase) very dark brown (holotype) to slate-grey or greyish-black (southern Africa), dark sepia brown (Kenya); hairs unicoloured or with darker base. Ventral pelage same as dorsal pelage, or slightly paler. Pelage may become rusty-red or rusty-brown (orange-phase) prior to being moulted: new pelage is in grey-phase. Head high-domed; crown and forehead with thick, erect velvety pelage, which conceals most of posterior surface of ears and dorsal surface of muzzle. Muzzle narrow; nostrils very small. Ears dark grey or blackish-brown; relatively short (24.5 [22–28]% of FA); roughly triangular, tip rounded. Tragus moderately long, 47.8 (33–60)% of E; basal two-thirds parallel-sided, posterior margin becoming convex near tip; tip rounded. Wings moderately long and narrow, very dark grey, blackish-brown or black; second phalanx of third finger ca. three times longer than the first; first phalanx of third finger angled forward so third finger appears bent. Interfemoral membrane large, very dark grey or black; calcars stout. In South Africa (at least), TL comparatively long (113.6 ± 3.5 mm) and hindfeet comparatively short (9.1 ± 0.6 mm) (cf. *M. fraterculus*). Skull small for an African *Miniopterus*. Profile of forehead region (viewed laterally) very strongly concave; braincase elevated (as in all *Miniopterus*).

Geographic Variation Two subspecies are recognized by Koopman (1994) and Simmons (2005), but they do not apparently vary in size:

M. n. arenarius: Sudan (and extraliminally Arabia) to Zimbabwe. FA: 45 (42–46) mm, n = 24; GLS: 14.4 (14.0–15.0) mm, n = 11.

M. n. natalensis: South Africa. FA: 45 (43–46) mm, n = 21; GLS: 14.3 (13.6–14.9) mm, n = 11.

Similar Species African *Miniopterus* are very difficult to distinguish (Table 30, p. 712):

Miniopterus minor. Forearm shorter (39.8 [37–42] mm). Skull sometimes smaller (GLS: 13.6 [11.1–14.5] mm; C–M³: 5.3 [4.1–5.6] mm).

M. fraterculus. In the discriminant function of Stoffberg *et al.* (2004) (see Genus *Miniopterus*), *x* is positive.

M. schreibersii. Possibly almost always larger in areas of sympatry (e.g. in Zimbabwe and Malawi, FA: 46.8 [46–49] mm; GLS: 16.2 [15.9–16.5] mm; C–M³: 6.11 [6.0–6.2], *n* = 18). Ear more rounded. Possibly very widely distributed, but this is controversial (see Genus *Miniopterus*).

M. inflatus. Forearm almost always longer (48.3 [45–52] mm). Skull longer (GLS: 16.9 [16.0–17.8] mm).

Distribution Endemic to Africa. Widespread, mainly in the Sudan Savanna, Afromontane–Afroalpine, Somalia–Masai Bushland, Coastal Forest Mosaic, Zambezian Woodland, Highveld, South-West Arid and South-West Cape BZs, from S Sudan and Ethiopia southwards through Uganda, Rwanda, Kenya and Tanzania, and in most of south-central and southern Africa from Angola to Malawi and southwards. Material from Ethiopia, Uganda and Rwanda needs confirmation using DNA technology (D. Jacobs pers. comm.). Records from Angola (Crawford-Cabral 1986) also need confirmation that they represent *M. natalensis* and not *M. schreibersii*.

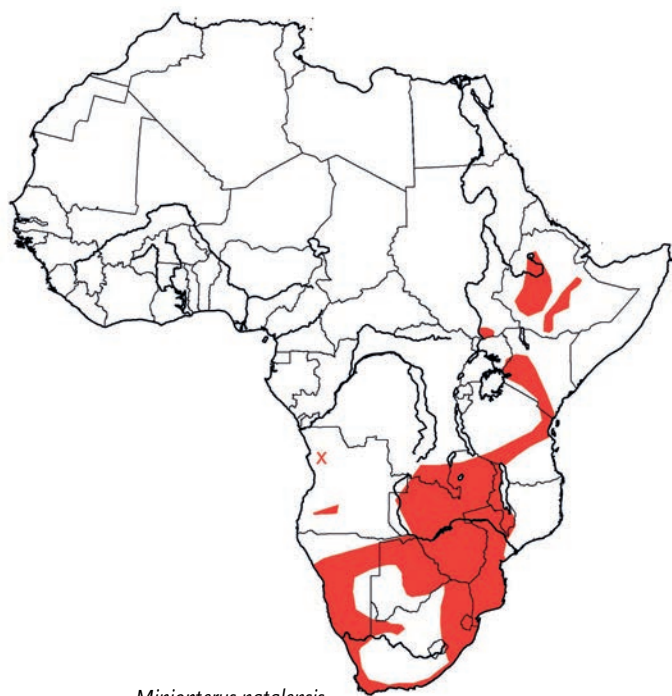

Habitat In Ethiopia, habitats include semi-desert grassland with *Acacia* scrub and volcanic caves, and areas of dense *Acacia* and broad-leaved scrub near limestone caves (Largen *et al.* 1974). In Kenya, recorded mainly from *Acacia–Commiphora* bushland and thicket; possibly also occurs in forest–savanna mosaics and afromontane vegetation but identity of specimens from these wetter habitats needs confirmation. In South Africa, occurs in a wide range of habitats including bushveld and grassland (Taylor, P. 1998). Tends to

avoid forests and, in more arid regions, is associated with standing or running water. Caves and/or similar underground day-roosts are apparently essential.

Abundance Uncertain. Sometimes very abundant in vicinity of suitable day-roosts, especially when numbers concentrate at maternity roosts. In South Africa, it is one of the most abundant cave-dwelling bats; apparently much more common than *M. fraterculus*.

Adaptations Aspect ratio very high; wing-loading low; flight characteristics similar to those of *M. fraterculus* (*n* = 1; M. Happold unpubl.). One individual sustained flight in a 1×1×1 m enclosure for up to three circuits/flight (10 flights). By day, roosts in dark caves or similar underground day-roosts including mine-adits and tunnels; clings or hangs freely to ceilings and walls and occasionally crawls into crevices. Also sometimes roosts by day in houses, rock crevices and hollow trees. At night, roosts in open buildings including verandas, pump-houses and garages (Rautenbach 1982). Selection of day-roosts is influenced by reproductive condition, and the microclimate and structure of the roosts (van der Merwe 1973a, Laycock 1976, Bernard 1980b, Bernard & Bester 1988, McDonald *et al.* 1990b, Brown & Bernard 1994). In South Africa, most ♂♂ and almost all ♀♀ migrate in autumn to higher altitude, inland caves with comparatively low temperatures (10.5–13 °C, sometimes 15.3 °C) in which they hibernate during May–Jul. These temperatures are higher than those generally accepted as suitable for hibernation (Brown 1999). In late winter, most migrate back to lower altitude caves, which are warmer (≥20 °C); migration distances of up to 260 km are known. Some hibernacula are occupied year-round. In summer-occupied caves, some individuals choose the coolest parts (20–24 °C) and become torpid during day, but most choose the warmest areas (around 30 °C) and remain alert and potentially active. Movements between summer-occupied caves are common. Some ♂♂ over-winter in these caves. A genetic study, using paternally inherited nuclear DNA markers and maternally inherited mitochondrial DNA markers, showed that both ♂♂ and ♀♀ of this migratory species tend to return consistently to the place where they were born, leading to constricted gene flow among subpopulations and hence to the existence of phenotypically distinct subspecific populations that are sympatric (Miller-Butterworth *et al.* 2003). In contrast, in most mammals (including other bats), ♂♂ disperse and only the ♀♀ are philopatric. For *M. natalensis*, the genetic structure of subpopulations is correlated with morphological differences between subpopulations and differences in the biomes they exploit, suggesting that each subpopulation has adapted to the particular conditions (including climate, availability of food) surrounding their roosts. Predicted mean maximum urine concentration is comparatively low (2937 mOsmol/kg), suggesting dependence on water for drinking (Happold & Happold 1988). Hibernacula sometimes have relative humidities fluctuating as low as 33%, so huddling to minimize evaporative water loss is probably obligatory. Furthermore, these bats often roost against moist surfaces.

Foraging and Food Forages opportunistically for flying insects by fast-hawking in open spaces, including over water, and also by slow-hawking in areas of moderate clutter: flexible flight (M. Happold unpubl.) and flexible echolocation make this diversity possible (Jacobs 1999). *Miniopterus natalensis* and/or *M. fraterculus* are attracted

Miniopterus natalensis

to swarms of insects over water and cattle enclosures. Diet includes mainly Coleoptera, Lepidoptera, Diptera and Isoptera (occasionally Homoptera, Orthoptera and others), with seasonal fluctuations in relative proportions of these insects in the diet (Fenton & Thomas 1980, Findley & Black 1983, Fenton 1985, McDonald *et al.* 1990a, as *M. schreibersii*). Where sympatric in South Africa, *M. natalensis* and *M. fraterculus* eat the same orders of arthropods, but the proportion of beetles in the diet is higher for *M. natalensis* (Miller-Butterworth *et al.* 2005).

Echolocation The calls of *M. n. arenarius* (identity not confirmed) in E DR Congo are broad bandwidth FM calls (shape not described) with end-frequencies 45–50 kHz (mean 48) (Novick 1958b). Calls with end-frequency 50 kHz were also recorded in Zimbabwe (Fenton & Thomas 1980, as *M. schreibersii*). At De Hoop Nature Reserve (Western Cape Province, South Africa), search-phase calls of bats identified as *M. schreibersii* (but currently considered to represent *M. natalensis*) were steep FM/QCF calls whose mean end-frequencies (minimum frequencies) and mean durations varied from cluttered to open habitats: 50.3 kHz and 2.2 ms in clutter, 43.3 kHz and 3.7 ms in open habitat near a cliff, and 37.5 kHz and 4.4 ms in more open habitat over a causeway (Jacobs 1999). The identity of these bats was confirmed genetically (Miller-Butterworth *et al.* 2003). At Knysna, South Africa, search-phase calls of *M. natalensis* have end-frequency 43.9 (43–47) kHz; peak-frequency 49.7 (47.6–50.9) kHz; call-duration 5.3 (3.9–6.1) ms (10 bats; Miller-Butterworth *et al.* 2005).

Social and Reproductive Behaviour Mostly roosts in very large groups (colonies); occasionally roosts singly or in smaller groups (van der Merwe 1973b, 1975; Laycock 1976). During autumn, ♂♂ and ♀♀ congregate in or near hibernacula, mate and then hibernate together, huddling in tightly packed clusters varying in size from a few individuals to ca. 4000. A few ♂♂ over-winter separately in summer-occupied roosts. In spring and summer, ♀♀ and ♂♂ roost together in great numbers in pre-maternity colonies, and then ♀♀ congregate in maternity colonies (sometimes but not always in the same roosts) where adult ♂♂ are absent or present only in very small numbers. Clusters of 50,000–100,000 have been observed in maternity colonies comprised of up to 260,000 individuals. Pregnant ♀♀, and lactating ♀♀ with neonates, tend to segregate into different clusters and, later, juveniles are left in separate clusters, which ♀♀ visit only briefly to suckle.

Reproduction and Population Structure Litter-size: one. Reproductive chronology is restricted seasonal monoestry with a period of delayed implantation, which varies from 2–4 months in duration depending on latitude and related differences in seasonal regimes (Bernard *et al.* 1996). At 24–26°S (former Transvaal, South Africa), copulation and conception peak in late Mar, implantation peaks in late Jul after a delay of ca. 4 months, and parturition peaks from mid-Nov to early Dec, i.e. ca. 8.5 months after fertilization (van der Merwe 1979, 1986). At 29–31°S (KwaZulu–Natal, South Africa), where summer ends a month later, copulation and conception occur in Apr, implantation occurs in Aug, and parturition occurs in Dec, i.e. 7.5 months after fertilization (Bernard 1980b). At 18–19°S in Zimbabwe, copulation occurs in mid-Apr to mid-May, implantation is delayed until early Jul, and parturition occurs between late Oct and

mid-Nov, i.e. 6–7 months after fertilization (Bernard *et al.* 1996). At 11°S (Shaba Province, SE DR Congo), copulation occurs in mid-Apr; implantation in late Jul after a three-month delay; parturition in Oct (Anciaux de Faveaux 1977). At 02° 18'S (Masalani, near Kibwezi, Kenya), births in Nov (O'Shea & Vaughan 1980). In South Africa, 90% of all ovulations are from the left ovary, and all implantations are in the right uterine horn (van der Merwe 1986). During the period of active foetal development (ca. 120 days) weight increase is exponential (van der Merwe 1979, 1981). One year, however, the rains failed during the last month of pregnancy (Nov), presumably causing a reduction in the abundance of insects, and this was correlated with slowing of foetal growth-rate, indicating that facultative retarded embryonic development can occur in this species (Bernard 1974). Mean birth mass is 2.7 g (27% of mother's mass), so young are proportionally heavier at birth than many other mammals (excluding other bats). Sex ratio at birth ca. 1 : 1 (van der Merwe 1973b).

Predators, Parasites and Diseases Predators include Barn Owls *Tyto alba* in South Africa (van der Merwe 1980). Ectoparasites of middle-sized *Miniopterus* spp. in Africa include bed-bugs *Afrocmex leleupi*, *Stricticmex anciauxi* (Hemiptera: Cimicidae); fleas *Oxypterus isomalus*, *Rhinolophopsylla capensis*, *R. ectopa* (Siphonaptera: Ischnopsyllidae); 23 species of bat-flies (Diptera: Nycteribiidae, Streblidae); five species of ticks (Acari: Ixodidae); and 14 species of mites (Acari: Spinturnicidae, Macronyssidae, Myobiidae, Trombiculidae, Chirodiscidae, Sarcoptidae, Gastronyssidae) (Anciaux de Faveaux 1984), but which of these parasites are hosted by *M. natalensis* is uncertain.

Conservation IUCN Category: Least Concern.

However, found in only a few sparse caves that are under threat from human disturbance (tourism).

Miniopterus schreibersii SCHREIBERS'S LONG-FINGERED BAT

Fr. Miniopière de Schreibers; Ger. Schreibers Langflügelfledermaus

Miniopterus schreibersii (Kuhl, 1817). Die Deutschen Fledermäuse. Hanau, p. 14. Kolumbács Cave [= Kulmbazer Cave = Columbäza Cave], ca. 44° 37'N, 21° 40'E, Banat, near Coronini, Rumania.

Taxonomy Originally *Vespertilio schreibersii*. A polytypic species that probably comprises a complex of several species (Horáček *et al.* 2000). Information in the literature concerning this species is often questionable because of the confusion with identification. Synonyms in Africa: following Koopman (1994), Peterson *et al.* (1995) and Simmons (2005), *dasythrix*, *smitianus*, *villiersi*. Following these authors, *M. natalensis* (including *arenarius*, *breyeri* and *scotinus*) is excluded from *M. schreibersii*. The forms *dasythrix* and *smitianus* are sometimes considered synonyms of *natalensis* (e.g. Meester *et al.* 1986) but others (e.g. Koopman 1994, Peterson *et al.* 1995, Simmons 2005) include them in *schreibersii*. Based on morphological evidence, the form *villiersi* is usually considered a subspecies of *M. schreibersii* but this needs confirmation from genetic information. Subspecies: four currently recognized in Africa. The status of *M. schreibersii* subspecies in sub-Saharan Africa, as summarized here, can only be clarified by future genetic work. Chromosome number (Tunisia): 2n = 46; aFN = 50 (Baker *et al.* 1974). In Italy, 2n = 46; aFN = 50 (Capanna & Civitelli 1965). In Yugoslavia, 2n = 46; aFN = 52 (Bickham & Hafner 1978).

Description Small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; bent-winged; five upper and six lower cheekteeth on each side; medium-large for African *Miniopterus* (FA: 46.1 ± 1.75 mm; TL: 114.3 ± 10 mm). Sexes similar. Pelage very soft, dense, lying flat dorsally; mid-dorsal hairs 7–9 mm; pelage on crown and forehead thick, erect and velvety, concealing most of posterior surface of ears and dorsal surface of muzzle. Dorsal pelage greyish-brown, grey or brownish-black depending on subspecies (see below); hairs unicoloured. Ventral pelage paler; hairs bicoloured, dark with paler tip. Head high-domed; muzzle short and narrow; nostrils very small. Ears greyish-brown to brown; relatively short (26.1 [17–35]% of FA, n = 5); roughly triangular, tip rounded. Tragus moderately long, parallel-sided; tip rounded. Wings moderately long and narrow, greyish-brown; second phalanx of third finger ca. three times longer than the first; first phalanx of third finger angled forward so third finger appears bent. Interfemoral membrane large, greyish-brown; calcars reaching one-third distance to tip of tail. Skull medium-sized for an African *Miniopterus*. Profile of forehead region (viewed laterally) very strongly concave; braincase elevated (as in all *Miniopterus*).

Geographic Variation Subspecies in Africa, based on Koopman (1994), Peterson *et al.* (1995) and Simmons (2005) include:

- M. s. schreibersii*: Morocco, Algeria, Tunisia and Libya (and extraliminally Europe). Dorsal pelage greyish-brown to grey. FA: 45.1 (43–47) mm, n = 50; GLS: 14.9 (14.5–15.5) mm; upper C–M³: 5.7 (5.5–5.9) mm, n = 26 (Algeria, Libya; Qumsiyeh & Schlitter 1982, Kowalski & Rzebik-Kowalska 1991).
- M. s. villiersi*: Guinea to DR Congo (Koopman 1994). Dorsal pelage greyish-brown to brownish-black. FA: 45.2 (43–47) mm; GLS:

15.9 (15.5–16.2) mm; C–M³: 6.0 (5.7–6.2) mm, n = 14 (Guinea, DR Congo; Peterson *et al.* 1995).

M. s. smitianus: described from Namibia (Thomas 1927b); Ethiopia to Namibia (Koopman 1994); Peterson *et al.* (1995) found morphological differences between populations from Namibia and Kenya/Ethiopia. Dorsal pelage (Namibia) 'smokey grey near mouse grey' (Thomas 1927b); (Kenya/Ethiopia) greyish-brown to brownish-black. FA: 45.6 (45–46) mm, n = 8; GLS: 15.5 (14.9–15.8) mm; C–M³: 5.7 (5.6–5.9) mm, n = 8 (Namibia; Peterson *et al.* 1995).

M. s. dasythrix: described from Eastern Cape Province, South Africa (Temminck 1840). Malawi to South Africa (Koopman 1994). Dorsal pelage greyish-brown to brownish-black. FA: 46.4 (46–48) mm; GLS: 15.9 (15.4–16.1) mm; C–M³: 6.1 (6.0–6.3) mm, n = 6 (South Africa; Peterson *et al.* 1995).

Similar Species African *Miniopterus* are very difficult to distinguish (Table 30, p. 712):

Miniopterus minor. Forearm shorter (39.8 [37–42] mm). Skull almost always smaller in some dimensions (GLS: 13.6 [11.1–14.5] mm; C–M³: 5.3 [4.1–5.6] mm).

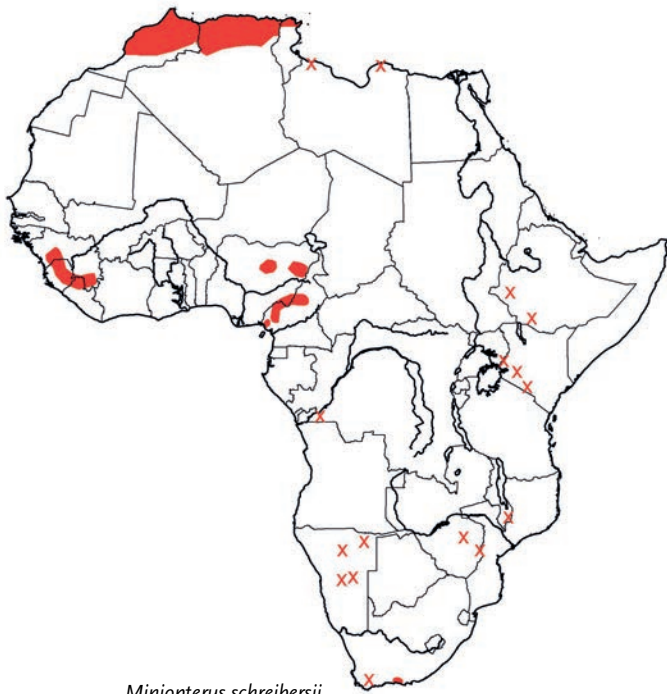

M. fraterculus. On average, smaller (FA: 43.3 [41–45] mm; GLS: 14.4 [13.3–15.5] mm).

M. natalensis. Possibly almost always smaller in areas of sympatry (e.g. in Zimbabwe and Malawi, FA: 44.5 [43–46] mm; GLS: 15.1 [14.7–15.5] mm; C–M³: 5.6 [5.3–6.0] mm). Ear less rounded. Distribution comparatively restricted.

M. inflatus. On average, FA shorter (48.3 [44–52] mm). Skull almost always larger (GLS: 16.9 [16.4–17.8] mm; C–M³: 6.5 [6.3–6.9] mm).

Distribution In Africa, the distribution appears very disjunct. Widespread in the Mediterranean Coastal and Afromontane–Afroalpine BZs of NW Africa (*M. s. schreibersii*). Also recorded in the Northern Rainforest–Savanna Mosaic in Guinea, Sierra Leone (USNM) and W Liberia, in the Sudan Savanna and Rainforest BZs in Nigeria, and in the Rainforest BZ and the Afromontane–Afroalpine BZ in Cameroon (*M. s. villiersi*). If *dasythrix* and *smitianus* are subspecies of *M. schreibersii*, this species also occurs in the Somalia–Masai Bushland, Zambezian Woodland, South-West Arid and South-West Cape BZs in eastern and southern Africa from Ethiopia to Namibia (Koopman 1994), but see Genus *Miniopterus* for further information. Extraliminally, *M. schreibersii* ranges from southern Europe eastwards to Afghanistan (Maeda 1982). Does not occur on Madagascar (Peterson *et al.* 1995). Subsequently recorded as far south as 34° 21'N in Tunisia (Dalhoumi *et al.* 2011): not mapped.

Habitat In NW Africa, *M. s. schreibersii* is recorded from sclerophyllous forests, semi-desert grasslands and steppes and from farmlands. In

*Miniopterus schreibersii*

Algeria, mist-netted over bushes and over water (Kowalski & Rzebik-Kowalska 1991). In sub-Saharan Africa, *M. s. villiersi* has been recorded from lowland rainforest and montane forest on Mt Cameroon from 1100 to 2100 m.

Abundance Uncertain. In Algeria (and presumably throughout geographic range in NW Africa), reported numerous in caves and other underground day-roosts (Kowalski & Rzebik-Kowalska 1991). Elsewhere in Africa, rarely recorded and probably uncommon or rare.

Adaptations Aspect ratio medium; wing-loading low; wing-tip roughly triangular (Norberg & Rayner 1987). Flight reminiscent of that of swallows; flight speed in open 50–55 km/h. Predictably can also fly slowly with great manoeuvrability. By day, roosts in caves and other underground day-roosts including mine-adits, cisterns, aqueducts and cellars. Hangs freely or clings in contact to ceilings, walls or conspecifics. Often shares roosts with *Rhinolophus* spp. and *Myotis* spp. In Algeria, becomes torpid during day in autumn (Kowalski & Rzebik-Kowalska 1991), and hibernates in winter (Weber 1912). In Europe, hibernates from Oct (?) to end of Mar; preferred temperatures 7–12 °C; sometimes moves to different hibernacula (Schober & Grimmberger 1989). Also hibernates in Lebanon (Lewis & Harrison 1962). Often migrates from hibernacula to summer-roosts; in Algeria, some caves are occupied year-round.

Foraging and Food In Europe, forages for flying insects by fast-hawking and slow-hawking, 5–20 m above ground, in open areas, often far from the day-roost (Macdonald & Barrett 1993). Food includes moths, gnats and beetles.

Echolocation No information for this species in Africa. In Italy, call-shapes include: (a) smooth steep/shallow FM (the shallow component becoming QCF); and (b) QCF (Russo & Jones 2002).

Social and Reproductive Behaviour In Algeria, roosts singly, in pairs or in small groups (Kowalski & Rzebik-Kowalska 1991); in Europe, sometimes roosts in colonies of up to 40,000 individuals. In Algeria, in autumn and winter, individuals huddle in tight all-male or male-female clusters, sometimes on top of each other. In summer, ♀♀ segregate and form maternity colonies in maternity roosts. Except when suckling their young, ♀♀ roost together in clusters, with most of the young in separate, peripheral clusters. Apparently, when the young become volant, they start roosting with the adult ♀♀. Towards the end of the lactation period, some adult ♂♂ begin roosting with ♀♀ and their young. At least two vocalizations, audible to humans, are known.

Reproduction and Population Structure Litter-size: one. At 36° 38' N (Aokas, N Algeria), reproductive chronology is restricted seasonal monoestry with parturition from mid-Apr to late Jun; earlier in west than in east (Kowalski *et al.* 1986). In Europe, copulation, ovulation and fertilization occur in autumn; implantation is delayed and gestation is 8–9 months (Schober & Grimmberger 1989).

Predators, Parasites and Diseases Found once in owl pellets in Algeria (Kowalski & Rzebik-Kowalska 1991). Ectoparasites in NW Africa include bat-flies *Nycteribia pedicularia*, *N. latreillei*, *N. schmidli*, *N. vexata*, *Penicillidia dufouri*, *P. conspicua*, *Phthiridium biarticulatum* (Diptera: Nycteriibidae), *Brachytarsina africana*, *B. kollari* (Diptera: Streblidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Near Threatened (based on data from North Africa, West Africa and extraliminally).

Based on overall population declines and range contractions, this species almost qualifies as Vulnerable.

Subfamily KERIVOULINAE – Woolly Bats

Kerivoulinae Miller, 1907. Bull. U.S. Nat. Mus., 57: 232.

Diagnostic combination of characters: second phalanx of third finger ca. as long as the first; braincase high and rounded; ears funnel-shaped with deep emargination below tip (Figure 116c); tragus long, narrow and sharply pointed (Figure 116j, k); six upper cheekteeth. Pelage woolly. Partly reviewed by Hill (1965, 1977b) and Corbet & Hill (1992). There are two genera:

Kerivoula (7 species in Africa). Posterior margin of tragus without deep, parallel-sided notch near base, skull with interorbital region

markedly constricted (Figure 153), outer upper incisor small but comparatively well developed, upper canine not grooved or only faintly grooved (see also genus *Kerivoula*).

Phoniscus (?1 species in Africa). Posterior margin of tragus with deep, parallel-sided notch near base, skull with interorbital region not markedly constricted, outer upper incisor rudimentary, upper canine conspicuously grooved (see also genus *Phoniscus*). The only record of this genus in Africa, *P. aerea*, is very dubious.

Meredith Happold

Figure 153. African *Kerivoula*. (a) Flight membranes and bones of wing, hindfoot and tail (e.g. *K. argentata*). (b) Semi-frontal view of left ear and tragus (e.g. *K. lanosa*). (c) Tragi of (c) *K. lanosa muscilla*, (d) *K. phalaena* and (e) *K. smithi* (after Rosevear 1965). (f) Ventral view of an interfemoral membrane with comb-like fringe of stiff hairs (*K. argentata*). (g) and (h) Lateral and dorsal views of skull (*K. argentata*; TM 3786; based on photos by T. Kearney). (i) Ventral view of skull (*K. smithii*; based on Allen 1917, as *K. cuprosa*).

GENUS *Kerivoula*

Woolly Bats

Kerivoula Gray, 1842. Ann. Mag. Nat. Hist., ser. 1, 10: 258. Type species: *Vespertilio pictus* Pallas, 1767.

A polytypic genus with 19 species, of which seven are endemic to Africa, and 11 occur in the Indo-New Guinea Region (Simmons 2005). Sometimes considered to include *Phoniscus* as a subgenus. Diagnostic combination of characters (African species): six upper cheekteeth (as in *Cistugo*, *Myotis* and *Phoniscus*), pelage woolly, frizzled, sometimes frosted; posterior margin of tragus with or without a shallow emargination near base (cf. *Phoniscus*); skull with rostral and anterior palatal emarginations long and narrow (cf. *Phoniscus*); interorbital region markedly constricted (narrower than posterior part of rostrum); outer upper incisor comparatively well developed albeit smaller than inner upper incisor; upper canine not grooved or only faintly grooved; dental formula: $2^{133}/_{3133} = 38$. Second phalanx of third finger not greatly elongated (cf. *Miniopterus*). Three species have a comb-like fringe of short, stiff, bristle-like hairs on or near the posterior margin of the interfemoral membrane. At least three (perhaps four) of the African species have frosted pelage, which, together with the underlying colour, provides very effective camouflage when these bats are roosting. The skull has a relatively long, narrow, flattened rostrum and a high-domed, rounded cranium, which rises at a sharp angle from the plane of the rostrum, giving the lateral profile a characteristic 'shoe shape' (Figure 153). Zygomatic arches slender; no sagittal crest; lambdoid crests very weakly developed. Auditory bullae prominent. Inner upper incisor larger than outer; inner incisor can be unicuspid, bicuspid or tricuspid, but the cuspidation of this tooth as a means of recognizing species is questioned by Rosevear (1965). Upper canines slender and small. Anterior and middle upper premolars equal in size and shape, both much smaller and simpler in form than the posterior upper premolar. Inner and middle lower incisors tricuspid or sometimes with four cusps. Outer lower incisor unicuspid, bicuspid, tricuspid

or occasionally with four cusps. Selected characters of African *Kerivoula* are illustrated in Figure 153.

The taxonomy of some African *Kerivoula* has been controversial, especially the status of forms with a comb-like fringe of hairs on the interfemoral membrane. These include *argentata*, *eriophora*, *harrisoni*, *lanosa* and *muscilla*, all of which have been given specific status fairly recently by some authors including Rosevear (1965), Hayman & Hill (1971), Ansell (1978), Smithers & Wilson (1979) and Happold *et al.* (1987). The status of *K. eriophora* is still uncertain, partly because the holotype has been lost and partly because there is no certain information about some of its characters (see profile), but its specific status is provisionally retained here, and by Simmons (2005). The specific status of *K. argentata* and *K. lanosa* are apparently unchallenged but, following Hill (1977b), both *harrisoni* and *muscilla* are currently placed in *K. lanosa*.

Kerivoula are rarely mist-netted but, in Cote d'Ivoire, *K. cuprosa* and *K. phalaena* have been harp-trapped but not mist-netted (see profiles). It is also very difficult to capture *Kerivoula* from their day-roosts. Consequently, the apparent rarity of *Kerivoula*, and the dearth of information about them, may be artefacts of sampling success.

The seven African species can be distinguished by a combination of characters including the presence or absence of a stiff comb-like fringe of hairs along the edge of the interfemoral membrane, FA length, the colour of the dorsal hairs and the extent to which the dorsal pelage is frosted or not frosted (Table 31). The cuspidation of the outer lower incisor and inner upper incisor is included in this table-key but the extent of variation is not yet known for some species (data available for <3 specimens), and might not yet be fully known for at least some of the other species.

Meredith Happold

Table 31. Key to the African species in the genus *Kerivoula*.

| Comb-like fringe of hairs on interfemoral membrane | FA (mm) | Frosting on dorsal pelage | Colour of dorsal hairs (excluding hairs that are frosted) | Outer lower incisor | Inner upper incisor | Species |
|--|------------|---|--|--|----------------------------------|---------------------|
| Present | 28–39 | Conspicuous | Yellowish-fawn with dark brown at base and terminal quarter bright rusty-brown (perhaps occasionally pale sepia brown) | Usually tricuspid, sometimes with four cusps | Unicuspid, bicuspid or tricuspid | <i>K. argentata</i> |
| Present | 30–34 | Conspicuous or sometimes not very conspicuous | Dark sepia brown, golden-brown, greyish-brown or pale grey with dark brown at base | Bicuspid or tricuspid | Unicuspid or bicuspid | <i>K. lanosa</i> |
| Present | 28, ca. 32 | Probably absent | Pale 'earth-grey' with white tip | Bicuspid ^a | Tricuspid ^a | <i>K. eriophora</i> |
| Absent | 32–36 | Conspicuous | Blackish or dark brown | Unicuspid | Bicuspid | <i>K. smithii</i> |
| Absent | 30–33 | Conspicuous | Dark brown with terminal third bright rusty-brown or chocolate brown | Tricuspid | Bicuspid | <i>K. cuprosa</i> |
| Absent | 25–28 | Absent | Pale reddish-brown, fawn-brown or greyish-brown; usually darker at base | Unicuspid | Unicuspid or bicuspid | <i>K. phalaena</i> |
| Absent | 28 | Uncertain, if present, probably not conspicuous | Dark brown to black with greyish-brown tip | Unicuspid ^a | Bicuspid ^a | <i>K. africana</i> |

^a Based on samples of <3 specimens and therefore the variation is not known.

Kerivoula africana TANZANIAN WOOLLY BAT

Fr. Chauve-souris peinte de Tanzanie; Ger. Tansania-Wollfledermaus

Kerivoula africana Dobson, 1878. Cat. Chiroptera Brit. Mus., p. 335. Coast opposite Zanzibar I., Tanzania.**Taxonomy** Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: ca. 28 mm; dorsal pelage greyish-brown or brownish-grey, frosting uncertain; posterior margin of interfemoral membrane without comb-like fringe of bristle-like hairs. Pelage woolly and frizzled. Dorsal pelage greyish-brown to brownish-grey, sometimes with silvery-grey streaks (but probably without conspicuous frosting); hairs dark brown to black with greyish-brown tip (Dobson 1878). Ventral pelage slightly paler. Head with narrow muzzle and high-domed crown; face nearly naked between eyes; long hairs arising from glands on muzzle; upper lip with fringe of hairs. Ears widely separated, funnel-shaped, pale brown; relatively short (46% of FA) but reaching beyond snout when laid forward. Tragus long (ca. 58% of E), tapering, sharply pointed. Eyes minute. Wings dark brown. Interfemoral membrane dark brown; dorsal pelage extending onto membrane close to body; posterior margin with few fine hairs only. Skull with high-domed cranium; frontal region sharply angular to plane of rostrum as in all *Kerivoula*. Inner upper incisor bicuspid; outer upper incisor unicuspid or bicuspid (with small or large basal cusp), and almost reaching height of inner incisor. Anterior and middle upper premolars subequal; both smaller than posterior premolar. Outer lower incisor unicuspid. Lower premolars subequal.

Geographic Variation None.

Similar Species Three other African *Kerivoula* do not have a comb-like fringe of hooked, bristle-like hairs on posterior margin of interfemoral membrane (Table 31, p. 724):

Kerivoula smithii. Pelage conspicuously frosted. Forearm longer (32–36 mm). Outer lower incisor unicuspid.

K. cuprosa. Pelage conspicuously frosted. FA longer (30–33 mm).

K. phalaena. Dorsal hairs pale reddish-brown, fawn or greyish-brown, usually with darker base. Outer upper incisor ca. two-thirds height of inner incisor, and with only a minute secondary cusp at the internal base.

Distribution Endemic to Africa. Recorded from only three localities. Apparently endemic to the coastal forests and lowland Eastern Arc Mts of Tanzania (Cockle *et al.* 1998).

Habitat Wetter and drier evergreen and semi-evergreen coastal forests on hills near Tanzanian coast: four recorded in Genda Genda Forest in the north, and one in Tong'omba Forest in the south (Cockle *et al.* 1998). Also recorded from Morogoro (Swynnerton & Hayman 1951) without details of habitat.

Abundance Very rare in collections.

Remarks Very little is known about this species. A ♂ and three pregnant ♀ were found roosting together inside hanging epiphytes in thicket forest, ca. 2.5 m above ground (Cockle *et al.* 1998).

Conservation IUCN Category: Endangered.

Only known from two locations (three localities). Has a very small population in a well-surveyed area. The coastal forests, and those around Morogoro are being lost at a very rapid rate.

*Kerivoula africana*

Kerivoula argentata DAMARA WOOLLY BAT

Fr. Chauve-souris peinte argentée; Ger. Bunte Wollfledermaus

Kerivoula argentata Tomes, 1861. Proc. Zool. Soc. Lond. 1861: 32. Otjoro, Namibia.

Taxonomy Synonyms: *nidicola*, *zuluensis*. Subspecies: three. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: 35.1 (28–39) mm; dorsal pelage usually bright rusty-brown with conspicuous silvery frosting; posterior margin of interfemoral membrane with comb-like fringe of hairs. Sexes similar. Pelage woolly and frizzled (many hairs with hooked tips), extending onto dorsal surface of forearm and tibia; mid-dorsal hairs 7–9 mm, ventral pelage longer and fluffy. Dorsal pelage bright rusty-brown (possibly occasionally pale sepia brown) with conspicuous, almost iridescent, silvery frosting; hairs yellowish-fawn with dark brown at base and terminal quarter reddish-brown, often with silvery or white tip. Ventral pelage cream, dirty-white or white. Head high-domed; muzzle long, narrow, flattened, mostly hidden by facial pelage; snout prominent. Eyes minute. Ears widely separated, funnel-shaped with sharply pointed tip; outer margin with concavity below tip. Tragus long (ca. 60% of E), narrow, tapering to sharp point; base with shallow emargination below widest point. Wings and interfemoral membrane pale brown, translucent. Dorsal surface of proximal half of interfemoral membrane with sparse covering of hair; posterior margin (between tips of calcars) with comb-like fringe of bristle-like hairs that curve inwards like hooks (Figure 153f). Tail 92 (87–100)% of HB, $n = 9$.

Skull (Figure 153) delicate; braincase high-domed; rostrum narrow; frontal region sharply angular to plane of rostrum as in all *Kerivoula*. Inner upper incisor tall with 0–2 basal cusps; outer upper incisor shorter, with 1–2 basal cusps. Anterior and middle upper premolars subequal; ca. half height of posterior premolar. Outer lower incisor usually tricuspid but sometimes with four cusps (i.e. with two, or sometimes three, basal cusps arising from cup-shaped cingulum, which are less than half the height of the main cusp).

Geographic Variation Meester *et al.* (1986) (and others including Simmons 2005) recognize three subspecies:

K. a. argentata: SW Kenya, Tanzania, DR Congo (Katanga Province),

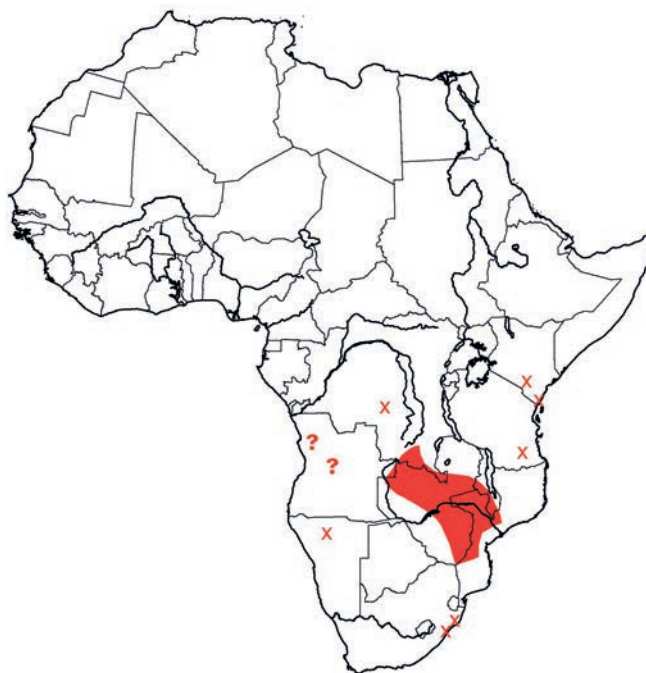

C Angola, N Namibia (Ovamboland), Zambia and Malawi.

K. a. nidicola: C Mozambique to Zambezi valley.

K. a. zuluensis: Zimbabwe, S Mozambique and KwaZulu–Natal.

Similar Species Only one other African *Kerivoula* (and possibly also *K. eriophora*) has a comb-like fringe of hairs on the posterior margin of the interfemoral membrane (Table 31, p. 724):

Kerivoula lanosa. Dorsal pelage dark brown to pale grey (with frosting), but not bright reddish-brown (with frosting). Ventral pelage sepia brown, grey to whitish. On average, FA shorter

Kerivoula argentata

(31.5 [30–34] mm). Skull shorter and more delicate (GLS: 12.6 [11.2–13.5] mm).

K. eriophora. Dorsal pelage frosted but not bright reddish-brown. Ethiopia.

Distribution Endemic to Africa. Recorded mainly from the Zambezian Woodland BZ, but also recorded from the Somalia–Masai Bushland BZ and the Southern Rainforest–Savanna Mosaic, and from the Coastal Forest Mosaic BZ in East Africa and in South Africa. Recorded from S DR Congo, SW Kenya, Tanzania, Zambia, Mozambique, Zimbabwe, Namibia and South Africa. Possibly recorded from Angola, but the records might represent *K. lanosa* (Crawford-Cabral 1986). Gaps in the distribution, especially in the Zambezian Woodland BZ, probably reflect insufficient sampling.

Habitat Evergreen forests, riverine forest and both mesic and dry woodland savannas. In southern Africa, tends to be confined to well-watered or riverine associations in dry country (Smithers 1983).

Abundance Uncertain. Although rarely encountered within its geographic range (e.g. Happold & Happold 1997), it may be more abundant than records indicate.

Adaptations Aspect ratio low; wing-loading very low (Aldridge & Rautenbach 1987, M. Happold unpubl.). Flight slow and fluttering, with very great manoeuvrability. Able to take off

from the ground; able to hover briefly; turns by banking (minimum radius <25 cm) and by stalling-and-twisting; one individual sustained flight within a 1×1×1 m enclosure for up to 32 circuits/flight (10 flights; M. Happold unpubl.). These abilities, together with efficient echolocation, probably enable *K. argentata* to avoid being captured in mist-nets. By day, has been found most often roosting in nests of weaver birds, including Masked Weaver *Ploceus velatus* and Spectacled Weaver *P. ocularis*, but has also been found roosting among clusters of dead leaves, on the rough bark of a tree, under the eaves of a hut, and on a wall sheltered by the eaves of a rondavel (Sclater 1901, Roberts 1951, Smithers & Wilson 1979). Frosted brown pelage provides roosting bats with effective camouflage: one cluster roosting under eaves resembled a mud-nest made by wasps (Shortridge 1934).

Foraging and Food No information. Based on wing morphology, flight characteristics and ‘whispering’ echolocation, this species is likely to forage near the ground in habitats cluttered by vegetation. The capture of one specimen ca. 1 m above ground (in a mist-net) supports this suggestion. Likely to forage by gleaning (as some Malaysian *Kerivoula* are predicted to do [Kingston *et al.* 1999]). Diet not known. The possibility that this species is a ‘spider specialist’ (as is *Phoniscus papuensis* in Australia [Schulz 2000, as *K. papuensis*]) invites investigation.

Echolocation Call-shape (flying in darkened laboratory) steep linear FM (Fenton & Bell 1981). Intensity very low; start-frequency ca. 120 kHz; end-frequency ca. 85 kHz; peak-frequency 90–118 kHz; maximum call-duration 2 ms. This species (and at least some other *Kerivoula* spp.) is a ‘whispering bat’, these being bats that echolocate with calls of very low intensity (<75 dB at 10 cm) (Fenton & Bell 1981). ‘Whispering’ echolocation is typical of nycterids, but *Kerivoula* spp. are the only African vespertilionids (for which information is available) that are whispering bats.

Social and Reproductive Behaviour Roosts singly, in pairs or in groups of up to five (Shortridge 1934, Smithers 1983). Up to three have been found, tightly huddled, in bird nests, and groups of 4–5 have been found hanging in tightly packed clusters, under eaves. One such group comprised five ♀♀.

Reproduction and Population Structure No information.

Predators, Parasites and Diseases No information.

Conservation IUCN Category: Least Concern.

This species is not well known but has a large geographic range and is difficult to sample. No specific threats identified.

Kerivoula cuprosa COPPER WOOLLY BAT

Fr. Chauve-souris peinte cuivrée; Ger. Kupferfarbene Wollfledermaus

Kerivoula cuprosa Thomas, 1912. Ann. Mag. Nat. Hist., ser. 8, 10: 41. Bitye, Dja River, Cameroon.

Taxonomy Synonyms: none. *Kerivoula cuprosa* has frequently been confused with *K. smithii* and was incorrectly listed as a synonym of *K. smithii* by Anciaux de Faveaux (1984). Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: 31.7 (30–33) mm; dorsal pelage dark or chocolate brown with frosting; posterior margin of interfemoral membrane without comb-like fringe of bristle-like hairs; inner upper incisor bicuspid; outer lower incisor tricuspid. Sexual dimorphism: no information. Pelage dense, woolly, frizzled (many hairs with hooked tips); extending onto dorsal surface of forearm and tibia; mid-dorsal hairs ca. 7–8 mm. Dorsal pelage dark or chocolate brown, with golden sheen or singed appearance

depending on angle of view; hairs dark brown with terminal third bright rusty-brown or chocolate brown; many hairs with pale-brown hooked tip. Ventral pelage duller brown; hairs dark greyish-brown with terminal third paler; tip of some hairs whitish or cream. Head high-domed; muzzle long, pointed, hidden by facial pelage. Eyes minute. Ears brown, widely separated, comparatively and relatively short for a vespertilionid (42 [39–47]% of FA); anterior border strongly convex; posterior border with angular concavity just below the tip. Tragus moderately long (51 [46–56]% of E), narrow, tapering to sharp point, curved outwards, its base with a small lobule above which there is an emargination. Wings and interfemoral membrane dark brown. Posterior margin of interfemoral membrane with thinly scattered curled hairs but no comb-like fringe of hooked, bristle-like hairs; proximal third of dorsal surface sparsely covered with hairs. Tail 114 (100–133)% of HB.

Skull delicate; braincase high-domed; rostrum narrow; frontal region sharply angular to plane of rostrum as in all *Kerivoula*. Upper incisors comparatively short (cf. *K. phalaena*, *K. smithii*). Inner upper incisor bicuspid, the secondary cusp ca. half the length of the main cusp. Outer upper incisor ca. half to two-thirds the height of inner incisor, either unicuspid or weakly bicuspid, secondary cusp orientated postero-internally. Outer lower incisor tricuspid; outer cusps arising from cup-shaped cingulum (thereby creating tricuspid appearance) and ca. half height of main cusp. Lower premolars subequal in height but anterior premolar broader than both middle and posterior premolar.

Geographic Variation No information.

Similar Species Three other African *Kerivoula* have no comb-like fringe of hooked, bristle-like hairs on posterior margin of interfemoral membrane (Table 31, p. 724):

Kerivoula smithii. Outer lower incisor unicuspid (cingulum not distinctly raised on both sides of main cusp). Upper incisors comparatively long. Slightly larger (FA: 34.1 [32–36] mm; GLS: 13.1–14.1 mm) and heavier (5.9–7.0 g). Tragus longer (7.3–9.0 mm).

K. phalaena. Pelage not frosted. Outer lower incisor unicuspid. Almost always smaller (FA: 25–30 mm; GLS: 11.6–12.5 mm; GWS: 7.2 [6.6–7.4] mm).

K. africana. FA shorter (28 mm). Pelage probably not conspicuously frosted.

Distribution Endemic to Africa. Recorded mainly from the Rainforest BZ (Western, West Central, South Central and East Central regions) with one record in the Northern Rainforest–Savanna Mosaic in Guinea and another in the Guinea Savanna BZ in Côte d'Ivoire. Known from only seven localities: Pic de Fon, Guinea; Tâi N. P. and Comoé N. P., Côte d'Ivoire; Bitye (Dja R.), Cameroon; Eala, Koteli and Wafanya, DR Congo (Thomas 1912a, Schouteden 1944 [partim], J. Fahr unpubl., RMCA). A specimen from Ghana, originally identified as *K. cuprosa* (Koopman 1989), has been re-identified as *K. lanosa* (Koopman *et al.* 1995). Another record from Kenya (Fort Warwick, HZM 1.2066, Harrison 1957c) has been re-identified as *K. smithii* (J. Fahr unpubl.). Also many of the records from DR Congo, originally published as *K. cuprosa* (Allen 1917a, Dollman 1914, Schouteden 1944 [partim], Hayman *et al.* 1966 [partim], Anciaux de Faveaux 1984 [partim] and references therein) have been re-identified as *K. smithii* (Koopman 1965, J. Fahr unpubl.).

Habitat Recorded from lowland rainforest, swamp forest and forest–savanna mosaic in the Guinea Savanna BZ (Comoé N. P., Côte d'Ivoire).

Abundance Uncertain. Appears to be very rare, but probably very difficult to catch in mist-nets and by other methods used in the past; in Côte d'Ivoire, four individuals were captured with harp-traps, but none were caught in mist-nets (J. Fahr unpubl.).

Remarks Wings broad; flight highly manoeuvrable; can hover for short periods. Possibly roosts among leaves as do other members of the genus. All specimens in Côte d'Ivoire were caught in dense vegetation with harp-traps at height of 1.5 m (n = 4). Likely to forage in cluttered

Kerivoula cuprosa

spaces and likely to be a gleaner. Diet not known but delicate skull and dentition indicates that it probably consists of soft-bodied and rather small arthropods. Echolocation calls are steep, broad-band FM calls (details not known). Ectoparasites include a mite *Olabidocarpus belsorum* (Acari: Chirodiscidae) (Anciaux de Faveaux 1984, as *K. smithii*). Nothing else appears to be known about this species.

Conservation IUCN Category: Data Deficient.

Only seven localities known. Could become threatened under criterion A4c because of loss of forest. Population trend not known. Major threats: loss and degradation of habitat as result of logging and agriculture.

Jakob Fahr

Kerivoula eriophora HEUGLIN'S WOOLLY BAT

Fr. Chauve-souris peinte d'Éthiopie; Ger. Heuglins Wollfledermaus

Kerivoula eriophora (Heuglin, 1877). Reise in Nordost-Afrika, 2: 34. Belegaz Valley, between Semian and Wogara, Ethiopia.

Taxonomy Originally *Nycticejus eriophorus*. Synonyms: none. A species of doubtful status. The holotype is lost, and presuming that this was the only information, Largen *et al.* (1974) referred it to *K. africana* from Tanzania, but Kock (1984) rediscovered a surviving syntype and concludes that it should be referred to *K. lanosa*. Yalden *et al.* (1996) also conclude that *eriophorus* is a junior synonym of *K. lanosa* and that it is a prior name for *K. l. harrisoni*. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: ca. 28–32 mm; dorsal pelage pale grey probably without frosting; posterior margin of interfemoral membrane with comb-like fringe of hairs. Very poorly known. Based on the original description by Heuglin (1877), the pelage is frizzled; the dorsal pelage is pale 'earth-grey'; hairs with white tip, and the ventral pelage is dirty white becoming more greyish-brown on flanks. Wings and interfemoral membrane blackish-brown. Ears with pointed tip. Tragus long (almost as high as tip of ear), thin and 'lanceolate' (sharply pointed). No other information given. Heuglin's description of the pelage is ambiguous: 'hairs with white tip' could imply frosting but, if by 'tip' he meant the terminal third or terminal quarter of each hair, the pelage would look white or whitish without appearing to be frosted. The pelage of the syntype (NMW 24573) does not look frosted; the hairs are bicoloured, medium brown with rather long whitish tip (B. Herzig pers. comm.).

The skull of the syntype is damaged; its shape and measurements cannot be obtained. Inner upper incisor tricuspid with one small cusp arising from the cingulum and another minute one near the tip of the main cusp. Outer upper incisor distinctly more than half height of inner incisor (cf. *K. lanosa*). Anterior and middle upper premolars subequal. Outer lower incisor bicuspid, the second cusp being small. (Dentition described by B. Herzig pers. comm.)

Geographic Variation Not known.

Similar Species Uncertain (see Table 31, p. 724):

Distribution Endemic to Africa. If distinct, only known from the Afromontane–Afroalpine BZ of the Ethiopian Highlands, Ethiopia. Recorded from the Belegaz Valley between Semian and Wogara in Abyssinia (= Ethiopia) at 12° 50' N, 38° 20' E.

Habitat The Belegaz Valley is a high altitude (2300–3300 m) site in *Erica arborea*/*Hypericum revolutum* scrub. This habitat is now much degraded by the growing of cereals.

Abundance Uncertain. Known only from the three original specimens collected prior to 1877. It has not been collected in Ethiopia since then, despite moderately extensive collecting.

*Kerivoula eriophora*

Remarks The three bats were found in the hanging nest of a sparrow or species of weaverbird. If they do represent a distinct species, nothing else is known about their habits.

Conservation IUCN Category: Data Deficient.

Kerivoula lanosa LESSER WOOLLY BAT

Fr. Chauve-souris peinte laineuse; Ger. Kleine Wollfledermaus

Kerivoula lanosa (A. Smith, 1847). Illustr. Zool. S. Afr. Mamm., pl. 50. 322 km (200 miles) east of Cape Town, Cape Province, South Africa.

Taxonomy Originally *Vespertilio lanosus*. Synonyms: *bellula*, *brunnea*, *harrisoni*, *lucia* and *muscilla* (Hill 1977b), but the status of these forms needs further investigation. Possibly also includes *eriophora* (see profile *K. eriophora*). Its relationship to the poorly known *K. africana* awaits elucidation. Subspecies: four. Chromosome number (South Africa): $2n = 28$; $aFN = 50$. X = large metacentric, Y = small acrocentric (Rautenbach *et al.* 1993). Happold *et al.* (1987) treated *harrisoni* (Malawi and Zambia) as a distinct species, and *lucia* as a subspecies of *K. harrisoni*.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: 31.5 (30–34) mm; dorsal pelage golden-brown, greyish-brown or pale grey, with frosting; posterior margin of interfemoral membrane with comb-like fringe of hairs; inner upper incisor unicuspid or bicuspid, outer lower incisor bicuspid. Sexes similar. Pelage fine, woolly and frizzled (many hairs with hooked tips); extending onto dorsal surface of forearm and tibia; mid-dorsal hairs 6–7 mm. Dorsal pelage variable, dark sepia brown, golden-brown, greyish-brown or pale grey; hairs with dark brown at base, many with a pale brown, cream, silvery or white tip giving pelage a frosted appearance (sometimes not very conspicuous). Ventral pelage similar or paler, sometimes whitish at least on chest and belly; hairs with basal half dark brown, medium greyish-brown or grey; some hairs with white tip. Head high-domed; muzzle long, pointed, hidden by facial pelage; snout prominent. Eyes minute. Ears widely separated, semi-translucent pale brown, comparatively and relatively short for a vespertilionid (37 [31–43]% of FA); funnel-shaped with pointed tips; outer margin with concavity below tip. Tragus long (68 (62–74)% of E, $n = 6$), narrow, tapering to sharp point, posterior margin with shallow notch below widest point; tip with a few short hairs (Figure 153b). Wings and interfemoral membrane semi-translucent, pale grey to pale brown; thumb long and slender. Dorsal surface of proximal half of interfemoral membrane with sparse covering of hair; posterior margin (between tips of calcars) with comb-like fringe of bristle-like hairs, which curve inwards like hooks. Tail 87 (70–100)% of HB, $n = 7$.

Skull delicate; braincase high-domed; rostrum narrow; frontal region sharply angular to plane of rostrum as in all *Kerivoula*. Inner upper incisors long, pointed, unicuspid or bicuspid (having a basal subsidiary cusp, which can be rudimentary to pronounced); outer upper incisor minute, usually unicuspid but sometimes with subsidiary cusp. Anterior and middle upper premolars subequal; both much smaller than posterior premolar. Outer lower incisor with a main cusp and cup-shaped cingulum, which gives tooth a bicuspid or tricuspid appearance.

Geographic Variation Four subspecies are recognized by Hill (1977b), Meester *et al.* (1986), Koopman (1994) and Simmons (2005):

K. l. muscilla: Liberia and Guinea to Ghana, Nigeria, Cameroon, Gabon, Central African Republic and N DR Congo. Inner and outer upper incisors usually unicuspid, but sometimes with a subsidiary cusp (J. Fahr pers. comm.).

K. l. harrisoni: Ethiopia to Kenya and Tanzania.

K. l. lucia: south-central Africa (S DR Congo [Katanga Province] to Malawi), southern Africa (Botswana, Zimbabwe and south to KwaZulu–Natal [South Africa]). Inner upper incisors bicuspid; outer upper incisors unicuspid (J. Fahr pers. comm.).

K. l. lanosa: S and E Cape Province, South Africa.

In contrast, Yalden *et al.* (1996) question the justification for recognizing subspecies and suggest variation in *K. lanosa* is clinal.

Similar Species Only one other African *Kerivoula* (and possibly also *K. eriophora*) has a comb-like fringe of hairs on the posterior margin of the interfemoral membrane (Table 31, p. 724):

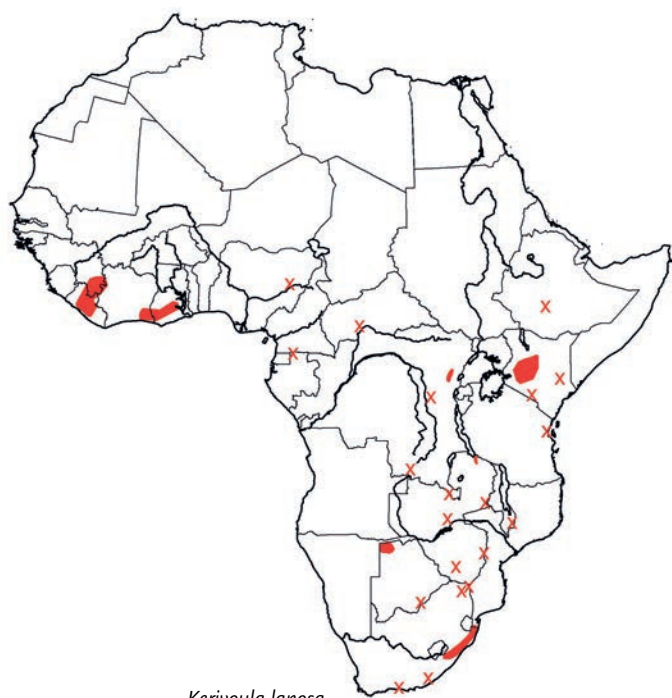

Kerivoula argentata. Dorsal pelage bright reddish-brown (with frosting). Ventral pelage cream, dirty-white or white. On average, FA longer (35.1 [28–39] mm). Skull longer and more robust (GLS: 15.7 [14.7–16.5] mm).

K. eriophora. Distinguishing characters (if any) not known: similar enough to be considered conspecific by Kock (1984). Presence of comb-like fringe of hairs on margin of interfemoral membrane is uncertain.

Distribution Endemic to Africa. Known from widespread, scattered records in the Rainforest BZ, the Northern Rainforest–Savanna Mosaic, Somalia–Masai Bushland, Coastal Forest Mosaic, Zambezian Woodland and South-West Cape BZs (with an outlying record in the Sudan Savanna BZ in Nigeria). Also occurs in or near the Afromontane–Afroalpine BZ of W Kenya (e.g. Nyeri and Cherangani Hills). Recorded from Liberia and Guinea to Ethiopia (but not in all countries), and southwards (on the eastern side of the continent) to South Africa (Hill 1997b and others).

Habitat Very varied. West Africa: apparently found mainly in rainforest (no details available); at Numan, Nigeria, found near the Benue R. in the Guinea Savanna BZ. Ethiopia: recorded between two of the lakes in the Rift Valley where the vegetation is predominantly *Acacia–Commiphora* bushland, at ca. 1300 m. Kenya: forests and *Acacia–Commiphora* bushland; no details available. Malawi: taken in a clump of bamboos in a forest full of bamboos at ca. 1000 m (R. C. Wood in Kershaw 1922). Southern Africa: evergreen forest, riverine forest and both wetter and drier woodland savannas (Cotterill 1996a). In drier areas, associated with riverine habitats.

Abundance Uncertain. Poorly represented in collections but this is possibly because their day-roosts are hard to find, they seem able to

Kerivoula lanosa

avoid being captured in mist-nets, and there have been comparatively few attempts to catch them in harp-traps.

Remarks Wings broad; based on wing morphology flight predicted to be slow and highly manoeuvrable as in *K. argentata*. The frosted pelage provides effective camouflage when this bat is roosting (e.g. Roberts 1951), and perhaps its woolly texture provides extra insulation from unfavourable temperatures likely to be experienced where these small bats roost in foliage. Most specimens have been taken from day-roosts in the woven-grass nests of weavers *Ploceus* spp.; some have been taken from nests made of cobwebs by sunbirds (Nectariniidae). A single ♀ was found in a sunbird nest, and a ♂ and two ♀♀ were found in a weaver nest (Smithers 1983). Two other nests contained two and

three individuals, respectively (not sexed) (Roberts 1951). Another nest contained a ♀ with two young, suggesting that she had given birth to twins. The echolocation calls of a ♂ (from Mberengwa, Zimbabwe) were steep linear FM in call-shape; start-frequency at least 170 kHz; end-frequency 100 kHz; intensity very low (F. P. D. Cotterill unpubl.). The calls are similar to those of Malaysian *Kerivoula* spp., which are predicted to forage by gleaning (Kingston *et al.* 1999). Diet not known; the possibility that this species is a 'spider specialist' (as is *Phoniscus papuensis* in Australia [Schulz 2000, as *K. papuensis*]) invites investigation.

Predators, Parasites and Diseases Ectoparasites include bat-flies *Basilia meridionalis*, *B. kerivoulae* (Nycteribiidae) (Anciaux de Faveaux 1984).

Conservation IUCN Category: Least Concern.

Kerivoula phalaena SPURRELL'S WOOLLY BAT

Fr. Chauve-souris peinte phalène; Ger. Spurrells Wollfledermaus

Kerivoula phalaena Thomas, 1912. Ann. Mag. Nat. Hist., ser. 8, 10: 281. Bibianaha, 216 m (720 ft), inland of Denkwā, Ghana.

Taxonomy Synonyms: none. Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: 25–28 mm; dorsal pelage various shades of brown, without frosting; posterior margin of interfemoral membrane without comb-like fringe of bristle-like hairs; inner and outer upper incisors unicuspid or weakly bicuspid; outer lower incisor unicuspid. Females with on average slightly longer forearms; sexes otherwise similar. Pelage dense, woolly, frizzled (many hairs with hooked tips); mid-dorsal hairs 6–7 mm. Dorsal pelage pale reddish-brown, fawn-brown or greyish-brown; not frosted; hairs

usually darker at base. Ventral pelage paler, less reddish. Head high-domed; muzzle long, pointed, hidden by facial pelage. Eyes minute. Ears medium brown, widely separated, comparatively and relatively short for a vespertilionid (47 [39–56]% of FA). Tragus long (50 [43–57]% of E), narrow, tapering to fairly sharp point. Wings blackish brown; pelage not extending to dorsal surface of forearm and tibia. Interfemoral membrane blackish-brown; posterior margin with thinly scattered hairs but no comb-like fringe of hooked, bristle-like hairs; very few hairs on dorsal surface. Tail 115 (92–138)% of HB.

Skull delicate; braincase high-domed, rostrum narrow; frontal region sharply angular to plane of rostrum. Upper incisors comparatively long (cf. *K. cuprosa*). Inner upper incisor unicuspid or with small secondary cusp at posterior base. Outer upper incisor shorter (ca. two-

thirds height of inner incisor), with only a minute secondary cusp at the internal base. Inner and middle lower incisors tricuspid; outer lower incisor unicuspid. Lower premolars subequal in height and breadth.

Geographic Variation No information.

Similar Species Three other African *Kerivoula* do not have a comb-like fringe of hooked, bristle-like hairs on posterior margin of interfemoral membrane (Table 31, p. 724):

Kerivoula smithii. Pelage conspicuously frosted. Inner upper incisor bicuspid, secondary cusp reaching ca. half to two-thirds height of main cusp. Larger (FA: 32–36 mm; GLS: 13.1–14.1 mm) and heavier (5.9–7.0 g).

K. cuprosa. Pelage conspicuously frosted. Outer lower incisor tricuspid. Almost always larger (FA: 30–33 mm; GLS: 12.3–13.1 mm; GWS: 7.9–8.4 mm).

K. africana. Dorsal hairs dark brown to black with greyish-brown tip. Outer upper incisor almost reaching height of inner incisor; unicuspid or bicuspid (with small or large basal cusp).

Distribution Endemic to Africa. Recorded mainly from the Rainforest BZ (Western, West Central and East Central Regions) with outlying records from the Afromontane–Afroalpine BZ in NE DR Congo and W Uganda, and from the Guinea Savanna BZ in Côte d'Ivoire. Distribution disjunct. Known from 16 localities in Guinea (Fahr & Ebigo 2003), Liberia, Côte d'Ivoire, Ghana, Cameroon, DR Congo and Uganda (Thomas 1912c, Aellen 1952, Kuhn 1965, J. Fahr unpubl.).

Habitat Mostly reported from lowland rainforest and coastal forest (11 localities). Also found in the (sub-) montane forests on the mountains flanking the Albertine Rift Valley at 700–2400 m in W Uganda and NE DR Congo, and in gallery forest within the Guinea Savanna BZ at Comoé N. P., Côte d'Ivoire. Recorded from a ravine forest within montane grassland at 1350 m on the Simandou Range, Guinea (Fahr & Ebigo 2003).

Abundance No conclusive information but apparently quite rare.

Remarks A ♂ from Kayonza (Uganda, ROM) was taken from the nest of a warbler (*Apalis* sp.) (E. Thorn pers. comm.). In Côte d'Ivoire, caught with harp-traps at a height of 1.5 m (n = 4) (J. Fahr unpubl.). Probably forages by gleaning. Echolocation calls are steep, broad-band FM calls (details not known).

Conservation IUCN Category: Least Concern.

Known from 16 localities within an apparently disjunct distribution. Could become threatened under criterion A4c (inferred) because of

Kerivoula phalaena

its restricted geographic range and deforestation within its range. Population trend not known.

Kerivoula smithii SMITH'S WOOLLY BAT

Fr. Chauve-souris peinte de Smith; Ger. Smiths Wollfledermaus

Kerivoula smithii Thomas, 1880. Ann. Mag. Nat. Hist., ser. 5, 6: 166. Old Calabar, SE Nigeria.

Taxonomy Synonyms: none. Sometimes spelled *smithi* but original spelling is *smithii* and *smithi* is an invalid emendation. Frequently confused with *K. cuprosa* (see Distribution). Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth on each side; ears funnel-shaped; pelage frizzled; upper canine not grooved; FA: 34.1 (32–36) mm; dorsal pelage dark brown with conspicuous frosting; posterior margin of interfemoral membrane without comb-like fringe of bristle-like hairs; inner upper incisor bicuspid; outer lower incisor unicuspid. Sexes similar. Pelage dense, woolly, frizzled (many hairs with hooked tips); mid-dorsal pelage ca. 9 mm. Dorsal pelage greyish-brown to dark brown with silvery sheen and silvery or straw-coloured frosting; hairs blackish or dark brown, many with a silvery or straw-coloured tip. Ventral pelage paler brown; hairs greyish-brown or blackish-brown, usually with a pale brown or fawn tip but some with a whitish-silvery tip. Head high-domed; muzzle long, pointed, partly hidden by facial pelage. Eyes minute. Ears widely separated, dark brown or blackish, comparatively and relatively short for a vespertilionid (39 [33–44]% of FA); deeply emarginated below tips. Tragus long (58 [53–64]% of E), tapering, curved outwards; base with small triangular lobule over a shallow emargination (Figure 153e). Wings blackish or dark brown; pelage extending with scattered hairs to dorsal surface of forearm, third digit, thumb, tibia and tail. Interfemoral membrane dark brown; posterior margin with sparse hairs but no comb-like fringe of hooked, bristle-like hairs. Tail 107 (92–131)% of HB.

Skull delicate; braincase high-domed; rostrum narrow; frontal region sharply angular to plane of rostrum. Inner upper incisor comparatively long (cf. *K. cuprosa*), bicuspid (with secondary cusp reaching ca. half to two-thirds height of main cusp) and taller than outer incisor. Outer upper incisor unicuspid or weakly bicuspid, the main cusp attaining the height of secondary cusp of inner incisors. Anterior upper premolar slightly higher than middle premolar but both much smaller than the posterior premolar. Inner and middle lower incisors tricuspid. Outer lower incisor unicuspid, cingulum not distinctly raised on both sides of main cusp and therefore does not appear cup-shaped. Lower premolars subequal in size.

Geographic Variation None recorded but data are limited.

Similar Species Three other African *Kerivoula* do not have a comb-like fringe of hooked, bristle-like hairs on posterior margin of interfemoral membrane (Table 31, p. 724):

Kerivoula cuprosa. Outer lower incisor with tricuspid appearance (cingulum distinctly cup-shaped and forming a cusp on each side of the main cusp). Upper incisors comparatively short. Often smaller (FA: 31.7 [30–33] mm; GLS: 12.3–13.1 mm) and lighter (4.0–4.5 g). Tragus almost always shorter (5.5–7.4 mm).

K. phalaena. Pelage not frosted. Inner upper incisor unicuspid or with small secondary cusp at posterior base. Smaller (FA: 25–30 mm; GLS: 11.9–12.5 mm) and lighter (2.2–5.0 g).

K. africana. Pelage probably not conspicuously frosted. Forearm shorter (28 mm, $n = 1$). Outer lower incisor tricuspid.

Distribution Endemic to Africa. Mainly found in the Rainforest BZ (West Central, South Central and East Central Regions) with one fairly isolated record in the central Congo Basin and two isolated records from the Afromontane–Afroalpine and the Somalia–Masai Bushland BZs in Kenya. Distribution disjunct. Known from 12 localities in Nigeria, Cameroon, DR Congo, Uganda (Mwela [Bugoma Forest]; LACM) and Kenya (Thomas 1880, 1912b, Eisentraut 1956, Harrison 1963b, Koopman 1965, Hayman *et al.* 1966 [*partim*], Rahm 1966, J. Fahr unpubl.). Records from Liberia and Côte d'Ivoire (Happold 1987, Koopman 1993, Koopman *et al.* 1995) have not been confirmed and probably represent either *K. phalaena* or *K. lanosa*, which occur in both Liberia and Côte d'Ivoire (J. Fahr unpubl.). The record from Fort Warwick (Eastern Aberdare Mts), published as *K. cuprosa* by Harrison (1957c), has been re-identified as *K. smithii* (J. Fahr unpubl.). The same is true for many of the specimens from DR Congo that were published as *K. cuprosa* (e.g. Allen 1917a, Schouteden 1944) but later re-identified as *K. smithii* by Koopman (1965), Hayman *et al.* (1966) and J. Fahr (unpubl.).

Habitat Mostly recorded from lowland rainforest (seven localities), but also found in mangroves at Old Calabar, Nigeria, Congolian swamp forests at Mafanya, DR Congo and (sub-) montane forests in the

*Kerivoula smithii*

Cameroon Highlands (ca. 900 m), the Albertine Rift Mts east of L. Albert in Uganda (ca. 1200 m) and the Eastern Aberdare Mts (ca. 2700 m) in Kenya. Also recorded from Bura, near Garissa (Harrison 1963b) on the Tana R., which, in this area, runs through riverine forest within the Somalia–Masai Bushland BZ.

Abundance Unknown but apparently localized and fairly rare (see also *K. cuprosa*).

Adaptations Some specimens were captured when they flew into a house at night; others were taken in a hut, and some were found when saplings near a stream were felled during the day (Lang & Chapin 1917b, Eisentraut 1956, Harrison 1957c, Rahm 1966).

Foraging and Food No information but diet likely to consist of small and soft-bodied arthropods. Other species of *Kerivoula* (from Malaysia and Australia) are known to glean their prey (Schulz 1997, 2000, Kingston *et al.* 1999).

Social and Reproductive Behaviour No information.

Reproduction and Population Structure Litter-size: one ($n = 5$). Reproductive chronology not known (data inconclusive). At ca. 0–1°S in inland Kenya, a pregnant ♀ was reported in Sep from Bura, near Garissa, and another in Dec from Fort Warwick (Harrison 1957c, 1963b). At 01°12'N in Uganda (Bugoma Forest), two ♀♀ were pregnant in late Nov (LACM). At 1–3°N in NE DR Congo (Akenge and Avakubi), two ♀♀ each with an attached young were found in early Oct (Lang & Chapin 1917b, RMCA).

Predators, Parasites and Diseases Ectoparasites include a mite *Rodhainyssus myotis* (Acari: Gastronyssidae) (Anciaux de Faveaux 1984 as *K. smithii*).

Conservation IUCN Category: Least Concern.

GENUS *Phoniscus*

Trumpet-eared Bats

Phoniscus Miller, 1905. Proc. Biol. Soc. Washington 18: 229. Type species: *Phoniscus atrox* Miller, 1905.

A polytypic genus with three species in SE Asia and/or Australia and one very dubious species described, probably erroneously, from Africa. *Phoniscus* is sometimes considered to be a subgenus of *Kerivoula* (e.g. Koopman 1993, 1994), but is considered distinct from *Kerivoula* by Hill (1965), Corbet & Hill (1980, 1992) and Simmons (2005). Diagnostic combination of characters: six upper cheekteeth; pelage woolly and frizzled; ears funnel-shaped; posterior margin of tragus with deep,

nearly parallel-sided notch near base; skull with rostral and anterior palatal emarginations short and wide; interorbital region not constricted (nearly as wide as the posterior part of the rostrum); outer upper incisor rudimentary and difficult to see; upper canine conspicuously grooved. The dubiously African species is *P. aeresa*.

Meredith Happold

Phoniscus aeresa DUBIOUS TRUMPET-EARED BAT

Fr. Chauve-souris peinte rousse; Ger. Zweifelhafes Trompetenohr

Phoniscus aeresa (Tomes, 1858). Proc. Zool. Soc. Lond. 1858: 333. 'Eastern coast of South Africa'.

Taxonomy Originally *Kerivoula aeresa*. Synonyms: none. Occurrence in Africa is very dubious (see Distribution). Chromosome number: not known.

Description Very small microbat without noseleaf and with tail more or less fully enclosed in interfemoral membrane; six upper and six lower cheekteeth; ears funnel-shaped; pelage frizzled; posterior

margin of tragus deeply notched near base (details below); upper canine grooved; dorsal pelage dark brown with conspicuous golden-bronze frosting; posterior margin of interfemoral membrane without comb-like fringe of stiff hairs. Pelage thick, woolly. Dorsal pelage dark umber-brown with shiny golden-bronze frosting; hairs with basal half grey-brown, terminal half yellowish-brown merging into dark umber-brown with shining golden-bronze tip. Ventral pelage

dark sepia brown with brownish-bronze frosting. Head with narrow muzzle and highly domed crown; face moderately hairy with woolly moustache on upper lip, and bare area between each eye and ear. Chin nearly naked. Ears widely separated, brown with shallow indentation near tip; tip rounded. Tragus long, tapering, sharply pointed; posterior margin with deep notch near base – the upper and lower margins of the notch are parallel-sided and the apex is rounded (cf. *Kerivoula*). Eyes minute. Wings and interfemoral membrane brown, indistinctly marked with punctated lines. Posterior margin of interfemoral membrane sparsely furnished with short bristle-like hairs, which, however, do not resemble a comb-like fringe.

Skull with interorbital region less constricted than in *Kerivoula*. Inner upper incisors long and pointed, outer upper incisor rudimentary and difficult to see; upper canine long, strong, angular and conspicuously grooved (cf. smooth in all species of *Kerivoula*); anterior premolar also long and pointed. (Description from Tomes 1858, Roberts 1951, Hill 1965.)

Geographic Variation None.

Similar Species None. No other African member of the subfamily Kerivoulinae has a tragus with a deep, parallel-sided emargination near base and conspicuously grooved upper canines.

Distribution Not mapped. Known only from two specimens in BMNH labelled ‘South Africa, eastern coast’ (Tomes 1858) and thought to have come from Knysna District (Roberts 1951). Because this species belongs to the mainly South-East Asian genus *Phoniscus*, which has no other representatives in or near Africa, it has

been suggested that the specimens actually came from the Malay Archipelago – possibly Sulawesi because Tomes also identified a specimen from Sulawesi (Celebes) as the same species (Roberts 1951, Laurie & Hill 1954, Hill 1965, Hayman & Hill 1971).

Remarks There is no other information about this species.

Conservation IUCN Category: Data Deficient.

Appendix: New Taxa 2005–2010

Soricidae

Surdisorex schlitteri Kerbis Peterhans, Stanley, Hutterer, Demos & Agwanda, 2009. Bonner zool. Beitr. 56: 178. Distribution: Kenya, eastern flank of Mt Elgon, ericaceous zone at 3150m.

Myosorex gnoskei Kerbis Peterhans, Hutterer, Kaliba & Mzaibuko, 2008. J. East Afr. Nat. Hist. 97: 23. Distribution: Nyika National Park, Malawi. Remarks: The trapping station was 200 m north of Chilinda Guest House (10°34' 37" S, 33°48' 30" E), 2285 m.

Sylvisorex akaibei Mukinzi, Hutterer & Barriere, 2009. Mammalia 73: 130. Distribution: Masako Forest Reserve (00°36' 304"N, 25° 15' 389" E, 338 m), Kisangani area, Tshopo District, NW Democratic Republic of Congo. Remarks: Primary forest.

Sylvisorex corbeti Hutterer & Montermann, 2009. Bonner zool. Beitr. 56: 202. Distribution: Chappa Waddi, (07° 01' N, 11° 41' E), 1900 m a.s.l., Gotel Mountains, SE Nigeria. Remarks: forest swamp.

Sylvisorex silvanorum Hutterer, Riegert & Sedláček, 2009. Bonner zool. Beitr. 56: 151. Distribution: Near Lake Bambili, Mt Lefo, Bafut Ngemba F. R. (5° 55' N, 10° 14' E), 1800–1900 m a.s.l., Bamenda Highlands, North West Province, Cameroon.

Chiroptera

Hipposideridae

Hipposideros tephros Cabrera, 1906. Boln R. Soc. Esp. Hist. nat. 6: 358. Distribution: Mogador, Morocco. Also occurs elsewhere in NW Africa (the Maghreb), West Africa and Arabian Peninsula (Vallo *et al.* 2008). Recently considered a subspecies of *H. caffer* (Sundevall, 1846) but restored to specific status by Vallo *et al.* (2007).

Rhinopomatidae

Rhinopoma cystops Thomas, 1930. Annals and Magazine of Natural History, ser. 7, 11: 496. Distribution: Luxor, Egypt. Remarks: Recently considered a subspecies of *R. hardwickei* Gray, 1831 (e.g. Van Cakenberghe & De Vree 1994) but restored to specific status by Hulva *et al.* (2007).

Molossidae

Mops bakarii Stanley, 2008. Acta Chiropterologica 10: 184. Distribution: Kipangani village (4.96487°S, 39.71456°E, 12 m a.s.l.), Ngezi Forest, Kaskazini Region, Pemba Island, Tanzania. Remarks: Found in attic of hospital. For further information, see profile *Tadarida brachyptera*.

Vespertilionidae

Eptesicus isabellinus (Temminck, 1840). Distribution: NW Africa and extraliminally, Iberian Peninsula (Juste *et al.* 2007). Remarks: Recently considered a subspecies of *E. serotinus* (Schreber, 1774) but restored to specific status by Benda *et al.* (2004c), Mayer *et al.* (2007), Artyushin *et al.* (2009) and Juste *et al.* (2009).

Scotophilus mhlanganii A cryptic sibling species of *Scotophilus dinganii* (A. Smith, 1833) found sympatrically in St Lucia Wetland Park and Skukuza, Kruger N. P., KwaZulu–Natal, South Africa, and at Leopard's Hill Farm, Lusaka, Zambia (Jacobs *et al.* 2006). It is distinguished genetically and by its echolocation calls and smaller size (Jacobs *et al.* 2006), and karyotypically (Eick *et al.* 2007). It is not yet described but has been tentatively named *S. mhlanganii* (Jacobs *et al.* 2007) and has been referred to as such in several publications including Jacobs & Barclay (2009). Further information in profile of *S. dinganii*.

Miniopterus africanus Sanborn, 1936. Field Museum of Natural History, Publications, Zoological Series 20: 111. Distribution: Shoa, Ethiopia. Also occurs in Eritrea, elsewhere in Ethiopia, Kenya, Tanzania, Botswana and Namibia. Remarks: Recently often considered a subspecies of *M. inflatus* Thomas, 1903, but its specific status was confirmed by Juste *et al.* (2007).

Cistugidae

The genus *Cistugo*, containing two species, both in Africa, was raised to familial status by Lack *et al.* (2010).

Miniopteridae

The subfamily Miniopterinae, containing many species of *Miniopterus*, including seven in Africa, was considered to justify familial status by Mein & Tupinier (1977) (based on morphological evidence) and by Hoofer & Van Den Bussche (2003) (based on mitochondrial ribosomal sequences), but the taxonomic position of these bats remained controversial (e.g. Simmons 2005). The validity of the Miniopteridae is now confirmed by additional genetic information (Miller-Butterworth *et al.* 2007).

Glossary

abbrev. = abbreviation

adj. = adjective

cf. = *confer*, compare with; as opposed to

Lat. = Latin

pl. = plural

q.v. = *quod vide*, 'which see'

acrocentric: describes a chromosome that has the centromere (*q.v.*) very near one end and which therefore appears to have only one arm (= telocentric [*q.v.*] for practical purposes).

ad libitum: (*Lat.*) as much as one likes; having unrestricted access to a resource (e.g. water or food).

aestivate: state of torpor (*q.v.*) induced by cold or drought; usually associated with a reduced metabolic rate and inactivity.

aFN: the total number of chromosomal arms in the autosomal chromosome complement of a species (*cf.* fundamental number [FN], which includes the chromosomal arms of the sex chromosomes as well as those of the autosomal [*q.v.*] chromosomes). Each metacentric (*q.v.*), submetacentric (*q.v.*) or subtelocentric (*q.v.*) chromosome is given a value of 2; each acrocentric chromosome is given a value of 1. *See also* fundamental number.

afroalpine: describes habitats and/or vegetation occurring above the treeline on African mountains. Includes montane grassland and heathlands.

afromontane: refers to mountainous regions in Africa, e.g. afromontane forests and afromontane grasslands.

agility: in bats, the rate at which a turn can be initiated during flight.

agouti: having an even mixture of pale- and dark-tipped hairs on the pelage creating a grizzled, speckled or 'pepper and salt' appearance.

Albertine Rift Valley: *see* Rift Valley (*q.v.*).

alisphenoid: bone in the skull.

allele: an alternative form of a gene. A diploid organism carries two alleles (which may be same or different) for each gene locus. At any one locus, there may be several possible alleles (although only two are present in a single organism).

allopatry (*adj.* **allopatric**): the situation where populations of the same or different species have non-overlapping geographic ranges; refers also to populations of the same, or different, species that are geographically separated. *cf.* sympatry (*q.v.*); syntopy (*q.v.*).

allozyme: one of a number of forms of the same enzyme having different electrophoretic properties and which are encoded by alternate alleles at the same genetic locus.

altimontane: collective term for the belts of ericaceous and afroalpine vegetation on the high mountains of tropical East Africa (White 1983).

altricial: describes young born in an undeveloped state.

alv.: (*abbrev.*) *see* C–M³ (*alv.*).

alveolus (*pl.* **alveoli**, *adj.* **alveolar**): small cavity; socket that houses the root of a tooth.

angular process: process at the posterior lower corner of the mandible; situated ventral to the coronoid process (*q.v.*).

antebrachial: anterior to the arm (forelimb).

ante-orbital: in front of the orbit (*q.v.*).

anthropophilic: loving or thriving with humans; inhabiting domiciles or day-roosts in man-made structures and buildings (including mines); thriving in habitats substantially modified by humans (e.g. towns, farmlands). *cf.* lithophilic (*q.v.*); phytophilic (*q.v.*).

antitragus: in bats, the lobe near the base of the outer margin of the pinna or conch of the ear (Figure 22).

apomorphy (*adj.* **apomorphic**): situation in which a novel character evolves from a pre-existing character. In cladistics (*q.v.*), an apomorphic character shared among two or more species (synapomorphy [*q.v.*]) indicates shared descent from a common ancestor and hence monophyly (*q.v.*). *cf.* plesiomorphy (*q.v.*).

arboreal: living above the ground (in trees and shrubs). *cf.* scansorial (*q.v.*); terrestrial (*q.v.*).

arm-wing: that part of the wing between body, hindlimb and fifth finger (= propatagium, *q.v.* plus plagiopatagium, *q.v.*). *cf.* hand-wing (*q.v.*).

aspect ratio: describes the width of a wing relative to its length. Calculated by dividing the square of the wingspan by the wing area. Narrow wings have high aspect ratios.

attenuation: the reduction of the intensity of a sound (e.g. echolocation call), which occurs as the sound travels away from its source. High frequencies attenuate more rapidly than low frequencies, therefore low frequencies can be heard and/or recorded further away from the source.

auctorum: (*Lat.*) of various authors.

auditory bulla: *see* tympanic bulla.

auditory meatus (*pl.* **auditory meati**): the external opening of the ear; the passage leading from the tympanic membrane (ear drum) to the external ear.

autapomorphy: derived trait uniquely characteristic of a taxon.

autosomal: pertaining to any chromosome other than the sex chromosomes.

axillary tuft: in bats, a tuft of hair arising from the axilla (armpit) (Figure 55b).

baculum (*pl.* **bacula**, *adj.* **bacular**): the os penis, or penis bone, which supports the penis in some mammals.

bandwidth: the difference in frequency between the highest and lowest frequencies of a sound (e.g. an echolocation call).

banking: in bats, a method of changing direction during flight without losing much speed or height; achieved by altering the form of the flight membranes so one wing has more lift than the other and the bat rolls; radius of turn is proportional to speed so banked turns are of comparatively large radius. *cf.* stall-and-twist turning (*q.v.*).

baobab: a tree, *Adansonia digitata*, having a disproportionately wide trunk, which, in mature trees, is often hollow.

- basal metabolic rate:** metabolic rate required for survival in the thermal neutral zone (*q.v.*); a state that requires the lowest expenditure of energy when at rest.
- basicranial axis:** a line drawn in the lateral view of the skull indicating the position of the floor of the braincase, in the median line (Harrison & Bates 1991).
- basicranium:** the base of the skull.
- basisphenoid:** cranial bone in middle of base of skull; the median posterior part of the sphenoid bone, forming part of the floor of the braincase.
- basisphenoid pit:** in bats, one of a pair of pits in the basisphenoid bone (Figure 101).
- bent-winged:** having two marked bends in the alignment of the bones comprising the third finger in the wings of all species in the genus *Miniopterus* (*cf.* aligned in a smooth shallow curve) (Figure 117c).
- bicuspid:** having two points or cusps (particularly of teeth).
- bifid:** divided by a shallow notch.
- bipedal:** body supported by the two hindlimbs; movement not using the forelimbs.
- biserial:** arranged in pairs (as in the cusps of molar teeth in some mammals, e.g. some rodents).
- blastula:** a hollow ball of undifferentiated cells (derived from a fertilized ovum by cell division), which represents one of the earliest stages of embryonic development.
- brachydont:** describes a premolar or molar tooth with low crowns. *cf.* hypsodont (*q.v.*).
- braincase (= cranium):** that part of the skull housing the brain; the part of the skull posterior to the front line of the orbits. *cf.* rostrum (*q.v.*).
- bristle hairs:** in shrews, long stiff hairs on tail (*see also* pilosity [*q.v.*]).
- brown fat:** in bats, adipose tissue (fat) specifically used for the generation of heat during arousal after hibernation.
- buccal:** pertaining to the cavity of the mouth.
- buccal pad:** an oval epithelial structure containing lipoid (fatty) substances, situated in each angle of the mouth of some bats between the cheek and the posterior molars.
- bushmeat:** meat for human consumption derived from non-domesticated mammals, birds and reptiles taken from their natural habitats and domiciles.
- bushveld:** savanna vegetation type characterized by a grassy ground layer and a moderately dense upper layer of shrubs and scattered trees.
- BZ:** (*abbrev.*) Biotic Zone.
- C or c:** (*abbrev.*) canine tooth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* canine.
- CF:** (*abbrev.*) constant frequency *cf.* FM (*q.v.*).
- c.u.:** (*abbrev.*) (*Lat. cum unguis* = with nail) measurement of the hindfoot when length of the nail on the claw is included in the measurement. Usually hindfoot is measured without the claw because claws may be broken or worn. When length of claw is included, it is conventional to record as 'HF c.u.'. *cf.* s.u. (*q.v.*).
- C–M¹, C–M², C–M³:** in golden-moles and bats, the length of the upper tooththrow, measured from the most anterior part of the canine to the most posterior part of the most posterior molar. For golden-moles, the most posterior molar is M² or M³. For microbats, the most posterior molar is M³; for megabats, M³ (and sometimes M²) is lost, and therefore the most posterior molar is either M² or M¹.
- C–M³ (alv.):** in bats, the length of the upper tooththrow measured at the level of the alveoli (*q.v.*), from the most anterior part of the canine to the most posterior part of the most posterior molar.
- calcar:** bony or cartilaginous spur arising from the ankle and, in bats, helping to support the hind margin of the interfemoral membrane (*q.v.*). Also called calcaneum.
- call-shape:** the way the frequency of a bat's echolocation call changes with time as shown on a sonogram (spectrogram).
- canine:** the most anterior tooth on the maxilla bone and in a similar position on the mandible; situated immediately posterior to the incisors; if incisors are absent, the most anterior tooth in the jaw. Unicuspid; tall and pointed in most mammals. Never more than one canine on each side of each upper and lower jaw; absent in some taxa.
- caniniform:** having shape and appearance of a canine tooth.
- caravanning:** in shrews, behaviour of young (fully furred and with the eyes open) when they form a line behind the mother, each young holding on to the rump of the individual in front. The young 'follow' the mother as she moves around outside the nest.
- cauda epididymides:** the ducts of the epididymides at the posterior end of the testes, which carry sperm from the testes to the vas deferens, which, in turn, carries sperm to the penis. Sometimes used to store sperm prior to copulation.
- CbL:** (*abbrev.*) *see* condylobasal length.
- CcL:** (*abbrev.*) *see* condylocanine length.
- Cenozoic (= Cenozoic Era):** geological era, ca. 65 mya to today, comprising the Quaternary and Tertiary Periods: the Age of Mammals.
- central Africa:** Cameroon (south of the Sanaga R.), Central African Republic (but only south of ca. 7°N), Equatorial Guinea, Gabon, DR Congo (except SE). Mainly rainforest habitats and rainforest–savanna mosaics.
- central parting:** in hedgehogs, a thin longitudinal area of spine-free skin in the centre of the forehead and bordered to left and right by normal spines; presence or absence is useful for identification (*see* Figure 5a).
- centromere:** the part of a chromosome where sister chromatids are linked together during mitosis.
- cf.** (in general usage): compare or compare with. In the context of descriptions, implies a difference or contrast: e.g. 'In *T. niveiventer*, ventral pelage white (*cf.* *T. thersites* in which the ventral pelage is dark brown).'
- cf.** (in taxonomy): precedes the specific name if there is uncertainty in the assignment.
- cheekteeth:** the premolar (*q.v.*) and molar (*q.v.*) teeth combined.
- choana (pl. choanae):** the openings of the internal nostrils on the skull, situated immediately posterior to the bony palate.
- chromosome:** one of the thread-like bodies within the nucleus of a cell, which carry the genes (genetic material) in linear order; each chromosome is composed of one long molecule of DNA (and two long molecules at cell division). Chromosomes occur in pairs (one from each parent) and are visible as rod-like bodies in cells that are dividing. The total number of chromosomes in a cell is expressed as the diploid number (2n).

- CI:** (*abbrev.*) condyloincisive length; in shrews, the length of the skull from the anterior end of the longest incisor tooth to the posterior end of the occipital condyles. *cf.* GLS.
- cingulum** (*pl.* **cingula**): ridge around the base of the crown of a tooth.
- clade:** branch of a phylogenetic tree containing the set of all organisms descended from a common ancestor.
- cladistic (analysis):** a methodology that provides a classification in which organisms are grouped in terms of the time when they had a common ancestor.
- cline** (*adj.* **clinal**): in context of geographic variation, a gradual and sequential change of a character(s) without a significant break such as would justify division into separate subspecies or species.
- CNL:** condylo-nasal length; measurement from the most anterior part of the nasal bone to the most posterior part of the occipital condyle (exoccipital) on the same side of the skull; a similar measurement to 'greatest length of skull'.
- cochlea** (*pl.* **cochleae**): in bats, a hollow structure, spirally coiled like a snail's shell, situated in the skull and containing the internal organ of hearing (Figure 23).
- Coleoptera:** taxonomic order containing the beetles (within the phylum Insecta).
- colony:** in bats, a group of individuals of the same species roosting together in close proximity (but not necessarily in contact). Applied here to groups of 15 or more individuals (*see* group size).
- comparatively:** used in the context of describing the size of one character compared with the size of the same character in a different species. Sizes described as small, medium or large (if range is divided into three) or very small, small, medium, large, very large (if range is divided into five). *cf.* relatively (*q.v.*).
- competitive exclusion:** the principle that two different species cannot indefinitely occupy the same ecological niche.
- concave:** having a curvature that curves inwards; having an outline or a surface curved like the interior of a circle or sphere. *cf.* convex (*q.v.*).
- concavity:** a concave depression in an outline or surface.
- conceptus:** embryo prior to implantation.
- conductance:** in thermal biology, the rate at which heat passes across a temperature gradient, e.g. the density and thickness of the pelage affects the rate at which body heat passes from the body to the outside. Thick pelage, which traps and holds air, results in low thermal conductance.
- condylar process:** process at the posterior upper corner of the mandible, which forms the lower hinge of the jaw articulation; fits into the glenoid fossa of the skull.
- condyle:** a rounded process on a bone, which articulates with a socket-like concavity in another bone.
- condylobasal length (CBL):** in bats, the length of skull from the most posterior point of one exoccipital condyle to the front of the premaxilla on the same side (Figure 23).
- condylocanine length (CCL):** in bats, the length of skull from the most posterior point of one exoccipital condyle to the front of the canine tooth on the same side (Figure 23).
- congeneric:** belonging to the same genus.
- connecting process:** the longitudinal structure arising from the central component of the noseleaf of bats in the family Rhinolophidae, that extends from the back of the sella (*q.v.*) to the base of the lancet (*q.v.*) (Figure 56). Its shape, viewed laterally, is a diagnostic character (Figure 59).
- conspecific:** belonging the same species.
- contiguous:** touching; sharing a boundary (as in geographic ranges).
- convex:** having a curvature that bulges outwards; having an outline or a surface curved like the exterior of a circle or sphere. *cf.* concave (*q.v.*).
- coprophagy:** the behavioural process of eating faeces as they are voided from the anus.
- copulatory plug:** plug formed in the vagina of the female after copulation; formed from seminal fluids of the male. Prevents or reduces the chance of sperm from another male(s) entering the female reproductive tract if the female copulates again soon after copulation with the first male.
- coronoid process:** angular pointed process on the upper margin of the mandible, situated anteriorly to the condylar process (*q.v.*); does not participate in the jaw articulation.
- corpus luteum** (*pl.* **corpora lutea**): a glandular mass of tissue on the surface of an ovary, that develops after the extrusion of an ovum from a Graafian follicle (*q.v.*); secretes the hormone progesterone.
- cotype:** originally synonymous with syntype but now used as synonym of paratype (*q.v.*).
- CR:** (*abbrev.*) *see* crown–rump length.
- cranial profile:** the shape of the cranium (that part of the skull which surrounds the brain) when viewed from the side.
- cranio-canine length (CrnC):** in bats, the distance from the most posterior part of the skull to the front of the upper canines (Figure 23). Often used instead of greatest length of skull (GLS) in bats of the families Rhinolophidae and Hipposideridae because, in these bats, the premaxillae are often lost during preparation of skulls.
- craniodental:** pertaining to the skull and teeth.
- cranium:** that part of the skull housing the brain. Also called braincase.
- crepuscular:** at, of, twilight, when light intensity is higher than at night but lower than during the day. *cf.* diurnal (*q.v.*); nocturnal (*q.v.*).
- CrnC:** (*abbrev.*) *see* cranio-canine length.
- crown area:** in bats, the area of the transverse section of a tooth just above the gum-line. For molars and premolars, can be assessed from their occlusal profiles.
- crown:** (1) top of head; (2) exposed part of a tooth (visible above gum), especially the grinding surface.
- crown–rump length (CR):** distance from the crown of head to the rump of a foetus (i.e. maximum length of a foetus in its natural form).
- cursorial:** pertaining to running. In bats, refers to scuttling or crawling in which the folded wings and hindlimbs are used for quadrupedal locomotion over a substrate (as opposed to flying, swimming or any other form of locomotion).
- cuspidate** (*adj.* **cuspidate**): a prominence or sharp point, such as on the occlusal surface of some teeth. *See also* t.
- Cyrenaica:** a region of north-east Libya. Includes the Cyrenaican Plateau and that part of the Mediterranean Coastal Biotic Zone between the plateau and the sea, as well as drier terrain south of the plateau.

cytochrome *b*: a protein involved in electron exchange in the mitochondria. It is the product of a gene in the mitochondrial genome. The sequence of this gene is often compared between species in phylogenetic studies to infer relatedness.

Dahomey Gap: the geographic region where savanna habitat extends southwards to the West African coast in E Ghana, Togo, Benin (formerly Dahomey) and extreme SW Nigeria. The presence of savanna forms a break (or gap) in the extensive Rainforest Biotic Zone, which extends along the West Africa coast from Sierra Leone to Cameroon. The Dahomey Gap is an important biogeographical barrier separating the faunas to the east and west of the Gap.

deciduous teeth: *see* milk teeth (*q.v.*).

Dega: Ethiopian word for the temperate agricultural/economic altitudinal zone, about 2300–3000 m, warm enough for cereal-based agriculture.

delayed implantation: a means of lengthening the interval between copulation and parturition by delaying the implantation of the blastula (*q.v.*), so that both copulation and parturition can occur in the most optimal seasons. Development to blastula stage is followed by a period of halted development lasting several weeks or months; then the blastula implants and embryonic development proceeds normally, usually without any further interruption, until the young is born.

dental formula: a simple numerical method of denoting the number of incisor (I), canine (C), premolar (P) and molar (M) teeth on one side of the upper jaw and lower jaw, and the total number of teeth. For example, the dental formula of a primitive mammal is $I^{3/3}, C^{1/1}, P^{4/4}, M^{3/3} = 44$, which means there are three incisors, one canine, four premolars and three molars on each side of the upper jaw and also the lower jaw, making a total of 44 teeth. The formula may also be expressed in the form $^{3143}_{3143} = 44$. Each incisor, premolar and molar is numbered according to its position in the tooth row; superscript numbers indicate upper jaw, subscript numbers indicate lower jaw (mandible), e.g. P^4 (upper fourth premolar), M_2 (lower second molar).

dichromatism: condition in which members of a species show one of only two distinct colours or colour-patterns.

dimorphism (*adj.* **dimorphic**): *see* sexual dimorphism.

diphyly: the derivation of a taxon from two separate lines of descent. *cf.* monophyly (*q.v.*)

diploid number (2n): total number of chromosomes (including sex chromosomes) in a somatic cell of an organism.

distal: the end of any structure furthest away from the mid-line of the body or furthest from the point of its attachment. *cf.* proximal (*q.v.*).

distichous: arranged in two rows; e.g. long hairs of the tail in some anomalurids and some dormice (as opposed to the hairs being evenly spread all around the tail).

diurnal: at, active in, daytime; when light intensity is high. *cf.* crepuscular (*q.v.*); nocturnal (*q.v.*).

DNA: (*abbrev.*) deoxyribonucleic acid; the very large self-replicating molecule which carries the genetic information of a chromosome; each molecule is composed of two complementary chains of DNA.

DNA hybridization: technique of comparing the similarity between two DNA molecules by reassociating single strands

from each molecule and determining the extent of double-helix formation. In phylogenetics, this technique is used to determine the relatedness of two or more taxa.

Doppler effect: variation in the pitch of a sound heard from a source of given frequency caused by any relative motion between the source and the observer.

Doppler shift: in bats, in context of echolocation, the change in pitch (frequency) of an echo resulting from the movement of the bat towards or away from the object reflecting the echolocation call, or from the movement of this object towards or away from the bat, or a combination of both.

dorsoventral (dorsoventrally): from dorsal to ventral surface; from back to belly of an animal.

duty cycle: in bats, in context of echolocation, the ratio of call duration to intercall interval; calculated by dividing the duration of a call by the time interval between the end of that call and the onset of the next call in the same sequence.

E: length of external ear or pinna (measured from tip of ear to the base of the ear conch nearest to the head). In bats, usually the length of ear from its tip to the notch in front of the orifice, but sometimes measured from the tip to the junction of the outer margin of the pinna (*q.v.*) with the head, or from the tip to the lower border of the external auditory meatus. This may account, in part, for wide ranges of ear measurements for some species when data are taken from diverse sources. For all mammals, length affected by preservation.

East Africa: Kenya, Uganda, Rwanda, Burundi and Tanzania.

eastern Africa: SE Sudan, Ethiopia, Eritrea, Djibouti, Somalia, Kenya, Uganda, Tanzania, Malawi (but only south of L. Malawi and east of the Shire R. Valley) and Mozambique (but only east of Malawi and north of the Zambezi R.).

echolocation: the use of reflected ultrasonic pulses of sound to perceive the surroundings (including obstacles, prey and other animals).

edaphic: influenced by conditions of soil or substratum.

emargination: a distinct notch or indentation.

embryo number: number of foetuses within the uterus or uteri of the female (as assessed by autopsy). Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* litter-size (*q.v.*).

endemic: restricted to, peculiar to, or prevailing in, a specified country or region.

endoparasite: a parasite that lives in the interior of an organism (e.g., nematodes, cestodes, blood parasites). *cf.* ectoparasite (*q.v.*).

entoconid cusp: the posterior cusp on the lingual (inner) side of a lower molar tooth. In bats, one of the posterior cusps on the lingual side of a lower molar tooth, located just anterior to the hypoconulid (*q.v.*) (Figure 138).

Eocene: geological Epoch (within the Tertiary Period); 55–38 mya.

epigeal: in zoology, living close to the ground.

epiphysis (*pl.* **epiphyses**): any part of a long bone that is formed from a different centre of ossification and which later fuses with the bone to form its terminal part.

epomophorines: all fruit bats in the Epomophorine section of Andersen (1912), which includes *Epomophorus*, *Epomops*, *Hypsignathus*, *Micropteropus* and *Nanonycteris*, *Plerotes*, *Casinonycteris* and *Scotonycteris*.

- evaporative water loss:** the loss of water from the body through the skin and/or the lungs. A mechanism used by mammals to reduce Tb (*q.v.*) when Ta (*q.v.*) is high. Excessive evaporative water loss may lead to dehydration if free (drinking) water is unavailable.
- exfoliating:** shedding flakes (e.g. of bark), or breaking into relatively thin slabs (e.g. of granitic rock).
- exoccipital condyles:** a pair of projections from the occipital bone on either side of the foramen magnum (*q.v.*) that articulates with the first vertebra of the spine. Also called occipital condyles.
- extant:** living at the present time. *cf.* extinct.
- F. R.:** (*abbrev.*) Forest Reserve.
- FA:** (*abbrev.*) in bats, the length of the forearm from the elbow to the distal end of wrist when the wing is folded. *See also* forearm.
- face-mask:** in hedgehogs, the pattern of white-coloured pelage on the anterior part of the face in hedgehogs.
- facultative:** having the capacity to switch from one mode of life or action to another depending on conditions or circumstances. *cf.* obligate (*q.v.*).
- female-defence polygyny:** a mating system in which males control access to females directly, usually by virtue of female gregariousness (Emlen & Oring 1977). Sometimes called harem-defence polygyny.
- fingers:** in bats, the digits (metacarpals and phalanges) of the wings (forelimbs). The first finger is referred to as the thumb.
- first toe:** in bats, the toe furthest from the mid-line (= outer toe); this is because the hindlimbs of bats are rotated so that the knees point backwards instead of forwards. In contrast, the first toe of all other five-toed mammals is the toe nearest the mid-line.
- flank:** the side of the body of a mammal.
- flank-stripe:** in bats, a stripe, in contrasting colour, running lengthwise along the flank. A ventral flank-stripe is just under the wing; a dorsal flank-stripe is just above the wing.
- fly-catching:** the foraging behaviour of bats that hang from a perch while they are searching for flying insects, fly from the perch to catch the prey in mid-air, and then return to the perch to eat and/or to resume searching.
- FM:** (*abbrev.*) *see* frequency modulated *cf.* CF (*q.v.*).
- FN:** (*abbrev.*) *see* fundamental number.
- folivore** (*adj.* **folivorous**): an animal that eats leaves.
- foramen** (*pl.* **foramina**): an aperture (which is usually small, round or elliptical) in a bone, or between bones, for the passage of a nerve, blood vessel or muscle.
- foramen magnum:** the large opening at the posterior end of the skull through which the spinal cord passes.
- forearm:** in bats, the wing-bones between elbow and fingers, comprised of radius, ulna and carpals.
- forehead region of skull:** in bats, that part of the dorsal profile of the skull (viewed laterally) encompassing the posterior part of the rostrum and the anterior part of the braincase.
- forest island:** *see* relict forest.
- form:** a neutral term for a single individual or taxonomic unit which may be employed without reference to the formal taxonomic hierarchy of categories; one of the varieties found in a polymorphic species.
- fossorial:** adapted for digging; burrowing. *cf.* subterranean (*q.v.*).
- fovea:** small pit or depression.
- frequency modulation:** in bats, in context of echolocation, increasing or decreasing frequency (pitch) during the emission of a call so that the call-shape (*q.v.*) is not a straight, horizontal line.
- frizzled:** in bats, describes the texture of pelage in which many of the hairs have a hook-shaped tip.
- frontal bone:** one of a pair of bones forming the anterior part of the braincase.
- frontal depression:** in bats, the saddle between the rostrum and frontal bones of the skull.
- frugivorous:** fruit-eating.
- fundamental number (FN):** an ambiguous term sometimes defined as (1) the total number of chromosomal arms in the full chromosomal complement of an organism (i.e. including the sex chromosomes), or (2) the total number of chromosomal arms found in the autosomal chromosomes only (i.e. excluding the sex chromosomes). When only the autosomal chromosomes are included, some authors (but not all) use aFN instead of FN to avoid ambiguity. For further details, *see* aFN.
- fynbos:** the heath shrublands characteristic of the Cape Floristic Kingdom (within the South-West Cape Biotic Zone) of South Africa. Dominant plants are sclerophyllous, evergreen, low (<3 m), bushy and fine-leaved, but there are also scattered taller bushes and, less often, very widely spaced trees. Contains an exceptionally high number of endemic species of plants. The three main components on nutrient-poor sandy soils are species of Ericaceae, Restionaceae and Proteaceae. Also includes 'renosterveld' (dominated by species of Asteraceae) on nutrient-rich silt or clay soils.
- G. R.:** (*abbrev.*) Game Reserve.
- gallery forest:** type of forest outlier (in a savanna region) found in narrow sheltered valleys and ravines on hillsides, where soils are moist enough, and conditions humid enough, to support rainforest trees (Rosevear 1953).
- garrigue:** a type of short, Mediterranean shrubland (White 1983).
- genotype:** genetic term to describe the genetic constitution of an individual inherited from its parents. *cf.* phenotype (*q.v.*).
- gestation:** the development of embryo/foetus, which takes place in the uterus; the period during which this development takes place. The gestation period is defined as the interval between conception and parturition (birth). Strictly speaking, the gestation period is not the interval between copulation (mating) and parturition (birth), although many authors take it to be this interval.
- glans penis:** the bulbous tip of the penis.
- gleaning:** in bats, the taking of resting or non-flying prey from surfaces including foliage, tree trunks, walls and ground. Hover-gleaners glean while hovering or flying slowly. Foliage-gleaners specialize in taking prey from foliage and tree trunks and are usually hover-gleaners. Ground-gleaners often land to catch prey but may also take it while flying slowly.
- glenoid fossa (= glenoid):** the cavity (fossa) in the squamosal bone of the skull for the articulation of the condyle of the mandible (lower jaw) in mammals; visible on lateral and/or ventral views of skull depending on the taxon.
- glenoid process:** in bats, refers to the raised rim on the posterior edge of the glenoid fossa (*q.v.*) (Figure 23).

GLS: (*abbrev.*) greatest length of skull (measured from anterior end of incisor teeth or nasal bone (whichever is most anterior) to the posterior end of the skull (occiput, occipital condyles or auditory bullae, whichever is most posterior). *cf.* CI. In bats, as measured from its most posterior point (posterior of occipital bone) to the most anterior part (anterior edge of premaxilla). Replaced by CrnC (*q.v.*) for bats in families Rhinolophidae and Hipposideridae.

Gondwana (= Gondwanaland): the southernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Africa, Madagascar, Antarctica, Australia, South America, the Indian subcontinent and the Arabian peninsula.

Graafian follicle: the structure in the mammalian ovary that contains the developing ovum, and from which the ovum is released at the time of ovulation.

gracile: lightly built. *cf.* robust

granivore (*adj.* **granivorous**): an animal that eats grains and seeds.

gregarious: living together in groups, flocks, herds.

Gregorian Rift Valley: *see* Rift Valley.

group-size: in bats, in the context of groups roosting together, two = two of same sex, pair = two of different sex, small = 3–15, medium-sized = 15–30, large = 30–100, very large >100. Groups (usually medium to very large in size) are sometimes referred to as colonies, especially in context of maternity colonies (*see* maternity colony).

guard hair: long thin bristle-like hairs, mainly on the back and flanks, which project beyond the soft hairs of the pelage; when present, conspicuous but never as numerous as soft hairs; probably tactile in function.

gular: pertaining to the upper part of the throat (the gula) as in gular gland, gular pouch, gular region.

GWS: (*abbrev.*) greatest width of skull, usually measured across the widest point of the zygomatic arches (*q.v.*). In shrews, which do not have zygomatic arches, the GWS is across the widest part of the cranium. In bats, usually the zygomatic width (*q.v.*) but sometimes the mastoid width (*q.v.*).

hallux: the first digit of the hindlimb; the big toe. In bats, the hallux is the outermost toe.

hammada: flat plain covered with pebbles of various sizes on a hard substrate in an arid environment. Much of the Sahara Desert is formed of hammada.

hand-wing: in bats, that part of the wing between the second and fifth fingers. Also called dactylopatagium. *cf.* arm-wing (*q.v.*).

hard-shelled: describes insects (e.g. eaten by bats) that have hard cuticles, e.g. beetles. *cf.* soft-bodied (*q.v.*).

harem: in bats, a social group of several adult females that mate (and usually roost) with one male. May include their progeny.

harmonics: e.g. in echolocation calls of bats, usually considered to be the lowest frequency of sound produced by the vocal cords (= fundamental frequency or first harmonic) and any other component of the call that is a whole number multiple of the fundamental. In this context, the second harmonic is twice the frequency of the first, and so on. (Note: some authorities do not consider the fundamental to be a harmonic and therefore consider that the first harmonic is the component having twice the frequency of the fundamental.)

harp-trap: trap designed to catch bats without harming them. Comprised of one or more banks of vertically-strung 'wires' made of fine, nylon fishing-line, suspended over a deep trough (made of canvas or similar material) into which bats fall after flying into the banks of 'wires'. Bats are prevented from climbing out of the trough by flaps of over-hanging material under which the bats usually settle and rest.

hastate: shaped like an arrow-head or spear-head; having a wide base and relatively longer, concave sides that taper to a bluntly-pointed tip.

HB: (*abbrev.*) length of head and body (measured from the tip of the nose to the most posterior point of the pelvis (anterior to the first tail vertebra).

helmet: *see* occipital helmet.

heterothermic: condition when the body temperature fluctuates in relation to the ambient temperature T_a (*q.v.*).

HF: (*abbrev.*) length of hindfoot (measured from the 'ankle bone' to the tip of the longest digit usually without including the claw). In bats, measured from back of heel to tip of longest claw (unless stated otherwise). *See also* c.u.; s.u.

hibernaculum (*pl.* **hibernacula**): a place, domicile or roost where an animal hibernates.

hibernation: a state of inactivity accompanied by a reduction in metabolic rate (below basal metabolic rate [*q.v.*]), lower T_b , and slow breathing. Occurs when T_a is low and food is scarce; usually lasts for weeks or months; not common in African mammals (*cf.* torpor).

high forest: rainforest that has matured, stabilized and reached the climax stage of succession.

highveld: high plateaux characteristic of inland southern Africa, dominated by grasses.

hind-border: in bats, the posterior edge of the wing, a term used when the edge is white or pale, in contrast to rest of the wing membrane. May extend from wing-tip to ankle, or be limited to the arm-wing (*q.v.*) or hand-wing (*q.v.*).

Holocene: geological Epoch (within the Quaternary Period) (*q.v.*) following the Pleistocene Epoch (*q.v.*); ca.11,000 mya to today. Sometimes referred to as the 'Recent' Epoch.

holotype (= type): the single specimen designated or indicated by the original author of the original description of a new species or subspecies, to be the standard reference to the essential characters of the new taxon. *see also* cotype (*q.v.*), lectotype (*q.v.*), neoparatype (*q.v.*), neotype (*q.v.*), paratype (*q.v.*), syntype (*q.v.*), topotype (*q.v.*) and type locality (*q.v.*).

homeothermic: describes an organism having a body temperature that is maintained at a constant level (within limits), independently of the ambient temperature T_a (*q.v.*).

home-range: the area (expressed in square metres, or square kilometres) routinely used by an animal for its day-to-day activities and requirements, and which contains the resources required for survival and reproduction. Within the home-range there may be a 'core area' or 'centre of activity' that is utilized more frequently than other parts (e.g. 80% or 90% of known time-based observations). *cf.* territory (*q.v.*).

homoplasy: similarity between different organisms or taxa resulting from evolution along similar lines (e.g. convergent evolution) rather than descent from a common ancestor.

hyoid: a small bone or bones in the throat located at the base of the tongue and supporting the muscles of the tongue.

- hyperthermia:** elevation of body temperature above normal limits due to increase in $T\hat{a}$ (*q.v.*) or increase in metabolic rate. *cf.* hypothermia (*q.v.*).
- hypocone:** in bats, the cusp on the posterior lingual corner of an upper molar that has a W-pattern of ridges.
- hypoconid cusp:** the posterior cusp on the labial (outer) side of a lower molar tooth (Figure 138).
- hypoconulid:** in bats, the most posterior cusp on the lingual (inner) side of a lower molar tooth (Figure 138).
- hypogeal:** living or growing underground.
- hypothermia:** drop in body temperature below normal limits; occurs in some small mammals when $T\hat{a}$ (*q.v.*) falls, and is a means of conserving energy in cold weather. *cf.* hyperthermia (*q.v.*).
- hypsodont:** describes a premolar or molar tooth with high crowns; has short roots.
- I or i:** (*abbrev.*) incisor (*q.v.*) tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* incisor.
- I. (pl. Is.):** (*abbrev.*) Island.
- I¹–M³:** the length of the tooththrow from the anterior end of the first upper incisor to the posterior end of the last molar. In taxa where the last molar is M¹ or M² (instead of M³), the measurement is I¹–M¹ or I¹–M².
- implantation:** the embedding of a blastula (*q.v.*) in the lining of the uterus.
- incertae sedis:** (*Lat.*) refers to a taxon of uncertain status and which may be taxonomically invalid.
- incisive foramen (pl. foramina):** in bats, paired foramina (sometimes three) located at the anterior end of the bony palate, just posterior to the incisor teeth.
- incisor:** tooth rooted in the premaxillary bone (most anterior bone of upper jaw) and in an equivalent position in the mandibular bone (lower jaw); always anterior to the canine teeth, if present. The number and form of the incisor teeth varies in different species. *See also* dental formula (*q.v.*).
- infraorbital foramen (pl. foramina):** foramen that connects the orbit (eye-socket) with the rostrum (premaxilla and maxilla bones); this foramen contains the masseter medialis muscle in some taxa. Also referred to as anteorbital foramen and antorbital foramen.
- inguinal:** situated in the groin, that is the area between the lower lateral part of the abdomen and the thigh.
- inner:** nearest to mid-line of body, e.g. inner incisor, inner margin of ear.
- insectivore (adj. insectivorous):** an animal that eats insects.
- inselberg:** isolated rocky hill; term used mainly in western Africa. *See also* jebel; kopje.
- interaual:** between the ears.
- interaual crest:** in bats, a tuft of erectile hairs posterior to the band connecting the ears of some species in the family Molossidae (Figure 95f, g).
- interfemoral membrane:** in bats, the flight membrane stretching from one hindleg to the other, sometimes enclosing or partly enclosing the tail, sometimes reduced to a very narrow flange around inside edge of legs (Figure 22). Also called uropatagium.
- interorbit (= interorbital constriction):** narrowest part of the skull between the orbits when viewed dorsally at the level of the frontal bones.
- interorbital breadth (IoB):** least breadth of the interorbital constriction (the narrowing of the skull [viewed dorsally] between the orbits) (Figure 23).
- interparietal:** bone (not paired) on dorsal surface of the skull, lying between and partly posterior to the parietal bones.
- interpterygoid:** the region between the two plate-like pterygoid bones (*q.v.*) that form part of the roof of the mouth.
- inter-specific:** between different species.
- intra-specific:** within one species; between members of the same species.
- invagination:** the formation of a cavity by the in-sinking of the outside wall or surface of a tissue or structure, thereby drawing an exterior layer into the interior of the structure to form the lining of the cavity; a cavity formed by the process of invagination.
- IoB:** (*abbrev.*) *see* interorbital breadth (*q.v.*).
- Isoptera:** taxonomic order containing the termites (within the phylum Insecta).
- isozyme:** any one of several different forms of an enzyme encoded by the same or different genes and which each differ in properties such as optimum pH or isoelectric point.
- iteroparous:** repeated reproduction throughout a season or a lifetime (*cf.* semelparous – reproduces once and then dies).
- Itigi thicket:** a type of vegetation found in Tanzania and Zambia, comprised of dense, deciduous, coppice-like, thornless shrubs, which interlace to form a continuous canopy, ca. 3–5 m in height, which is very dense when in leaf (White 1983). Occurs on specialized soils.
- jebel:** isolated rocky hill in savanna and arid habitats; term used mainly in northern Africa. *See also* inselberg (*q.v.*); kopje (*q.v.*).
- jugal:** bone of the skull, which forms the middle part of the zygomatic arch (*q.v.*); anteriorly joins the maxillary process (*q.v.*) of the maxilla bone and posteriorly joins the squamosal process of the squamosal bone.
- Kaokoveld:** area of sandstone and lava hills of the Namib Desert (Biotic Zone 11b) in NW Namibia, inland from the Skeleton Coast.
- Karoo:** southern African term for grassy dwarf shrubland on the semi-arid central plateau of the western half of South Africa at altitudes of 500–2000 m.
- karyogram:** a photographic representation of a karyotype (*q.v.*) as it appears at mitosis. Individual chromosomes are arranged in pairs from largest to smallest.
- karyological:** pertaining to the nucleus and chromosomes.
- karyotype:** the chromosomes in the cell of an animal. *See also* karyogram.
- kopje:** rocky hill with boulders, rock crevices and sparse vegetation; term used mainly in southern Africa. *See also* inselberg (*q.v.*); jebel (*q.v.*).
- K-selection:** selection for characteristics suitable in stable environments (slow development of young, small litter-size, relatively long time to maturity, relatively long life-span) *cf.* r-selection (*q.v.*).
- labial:** pertaining to the lips; situated near the lips; on the outer side of the teeth within the mouth. *cf.* lingual (*q.v.*).
- labially:** in the direction of the lips. *cf.* lingually (*q.v.*).
- lachrymal bone:** small bone in skull situated at the upper anterior margin of the orbit, near the lachrymal (tear) gland.
- lachrymal breadth:** in bats, the breadth across the rostrum dorsally at the lachrymal tubercles.

- lachrymal ridge:** in bats, a small ridge of bone, anterior to the orbit, on each side of the rostrum and sometimes forming a laterally-projecting lachrymal tubercle.
- lambdoid crest (= supraoccipital crest):** crest or ridge of bone running transversely across back of the skull at the junction of the dorsal (parietal) and posterior (occipital) bones of the braincase. May extend posteriorly above the occipital condyles (as in *Scutisorex*). In bats, can be absent, weakly developed, moderately developed or well developed in comparison with that of other species in the same family.
- lambdoid suture:** the line at the junction of the occipital and parietal bones of the skull. May be clearly defined in juveniles or obscured by complete fusion in adults, or by the formation of a lambdoid crest.
- lamina (pl. laminae):** in the context of premolar and molar teeth, a transverse row of cusps (e.g. t1, t2 and t3, or t4, t5 and t6, etc.), which, when worn, form a transverse ridge of bone and dentine across the tooth.
- lanceolate:** lance-shaped; slightly broad or tapering at base, and tapering towards a pointed tip.
- lancet:** the erect, subtriangular, posterior component of the noseleaf of bats in the family Rhinolophidae (Figure 56). Its shape (frontal view) is a diagnostic character (Figure 61).
- laryngeal echolocation:** echolocation using sounds produced by vocal chords in the larynx (as opposed to sounds produced in the mouth).
- lateral leaflets:** one or more pairs of leaflets, either rudimentary or well developed, situated below the anterior 'horseshoe' component of the noseleaf of bats in the families Rhinolophidae and Hipposideridae (Figure 56). Sometimes referred to as secondary leaflets (e.g. by Rosevear 1965, Csorba *et al.* 2003).
- Laurasia:** the northernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Europe, Asia (excluding the Indian subcontinent) and North America.
- lectotype:** a specimen chosen from syntypes (*q.v.*) to stand as 'the type' of a species or subspecies when no holotype (*q.v.*) was designated by the author who described the new species or subspecies.
- lek:** a traditional site where males gather for the sole purpose of attracting and courting females, and to which females come for the sole purpose of mating with the male of their choice.
- lenticular:** lens-shaped.
- Lepidoptera:** moths and butterflies and their larvae (caterpillars). In diets of bats, usually only refers to adult moths.
- limiting factor:** the principle that the growth or functioning of an organism is limited when any essential factor (or resource) is lacking or in short supply, regardless of the quantity available of any other factor (or resource). The principle may also be applied to the proliferation and/or distribution of a population or species.
- line (unit of measurement):** one-twelfth of an inch.
- lingual:** pertaining to the tongue; situated near the tongue; on the inner (tongue) side of the mouth. *cf.* labial (*q.v.*).
- lingually:** in the direction of the tongue. *cf.* labially (*q.v.*).
- lithophilic:** loving, or thriving amongst, stones, rocks; inhabiting domiciles or day-roosts in caves, on cliffs, or under or amongst rocks etc. *cf.* anthrophilic (*q.v.*); phytophilyc (*q.v.*).
- litter-size:** number of young born to a female. Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* embryo number (*q.v.*).
- lobule:** small lobe.
- localized movements:** movements of an animal within part or all of its home-range within a single day or within a limited period of time. *cf.* migration (*q.v.*); nomadic movements (*q.v.*).
- longitudinal:** lengthwise; running in a head to tail direction. *cf.* transverse (*q.v.*).
- lowveld:** savanna at lower altitudes below the Great Escarpment of South Africa, with vegetation consisting of a grassy lower layer and a woody upper layer of shrubs and/or trees, at either high density (woodland) or intermediate density (bushveld, *q.v.*).
- M:** (*abbrev.*) molar tooth or teeth. *See also* molar (*q.v.*).
- macchia:** a type of Mediterranean shrubland, usually tall, often impenetrable (White 1983). Also called maquis.
- Maghreb:** *see* north-west Africa (*q.v.*).
- mandible:** lower jaw.
- mandibular ramus:** one of the two branches (sides) of the mandible (*q.v.*); the two rami are joined at the mandibular symphysis.
- manoeuvrability:** in bats, refers to the space required by an individual to alter its flight path while flying at a fixed speed; inversely proportional to minimum radius of turn that the bat can attain, and also to wing-loading (*q.v.*) (Norberg & Rayner 1987).
- mastoid:** one of a pair of bones, often with a prominent process, situated near the posterior end of the skull behind the auditory meatus (*q.v.*).
- mastoid width (MW):** greatest width across mastoid region of skull (Figure 23), measured just behind the auditory meatus (*q.v.*).
- maternity cave:** a cave that is particularly suitable for the rearing of young bats.
- maternity colony:** in bats, a congregation of females that are giving birth and/or caring for their young, from which adult males are excluded (or exclude themselves). Also called nursery colony.
- maternity roost:** in bats, a day-roost that is particularly suitable for the rearing of young.
- maxilla (pl. maxillae):** one of the pair of bones in the skull which forms that part of each upper jaw in which the canine (*q.v.*) (if present) and cheekteeth (premolars and molars) (*q.v.*) are rooted.
- maxillary:** pertaining to the maxilla (*q.v.*).
- maxillary process:** projection of bone from the maxilla, which forms the anterior portion of the zygomatic arch (*q.v.*); usually orientated vertically to the anterior-posterior line of the skull.
- meatus:** a passage or channel; the opening of a passage.
- medial:** situated in the middle.
- megabat:** originally the common name for bats in the suborder Megachiroptera. The Megachiroptera is currently not considered monophyletic, and therefore neither of the two traditional Chiropteran suborders (Megachiroptera, Microchiroptera) is recognized by Simmons (2005). However, the name megabat is retained here, in non-taxonomical contexts, where it is relevant to distinguish between megabats (= fruit bats, family Pteropodidae) and microbats (bats belonging to all other families).
- melanistic:** having an abnormally large amount of black or dark pigment in pelage and skin.
- mesa:** Ethiopian word for the micro-habitat (usually on slopes) within afroalpine moorlands and grasslands, where it is higher

- and drier than surroundings areas, so dominated by (usually) *Alchemilla*.
- mesopterygoid fossa:** in bats, the generally U- or V-shaped depression on the ventral aspect of the skull posterior to the palate and between the pterygoid processes (*q.v.*).
- metabolic rate:** see basal metabolic rate (*q.v.*).
- metabolic water:** water produced by oxidative processes within the body; an important source of water for arid-adapted mammals when free (drinking) water and water within the food is in short supply or unavailable.
- metacarpals:** the long bones of the hand, situated between the carpal bones of the wrist and the proximal phalanges of the fingers; the most proximal of the long bones that comprise the fingers in the wings of bats.
- metacentric:** describes a chromosome with the centromere (*q.v.*) at or very near the middle of its length, so there are two arms of equal or almost equal length (ratio not greater than 1 : 1.1). *cf.* submetacentric (*q.v.*).
- metacone:** the posterior labial (external) cusp of an upper molar tooth.
- metatarsals:** the long bones of the foot, situated between the tarsal bones of the ankle and the most proximal phalanges of the toes.
- microbat:** originally the common name for bats in the suborder Microchiroptera. Retained here as the common name of bats in all families except the family Pteropodidae (= megabats, = fruit-bats). *See also* megabat and see text, order Chiroptera.
- microcomplement fixation:** in molecular evolutionary studies, species can be compared by the extent to which antibodies to the proteins of one species cross-react to the proteins of another species. The extent of cross-reaction is indicative of the similarity of the proteins and, by inference, the evolutionary affinity of the two species. Albumin is a protein commonly used for these studies.
- migration:** movements of species that travel, predictably and more-or-less directly, from one habitat to another (and back again), along predetermined routes, in response to seasonal changes in climate, food supply or any other resource. *cf.* localized movements (*q.v.*); nomadic movements (*q.v.*).
- milk teeth:** teeth (usually simple) occurring in newborn mammals, or appearing soon after birth, and preceding the permanent teeth of the adult animal. Also called deciduous teeth. In bats, they are tiny, sharp-pointed spicules, shaped to enable neonates to cling very firmly to the nipples of the mother during flight.
- mine-adit:** horizontal or near-horizontal tunnel in a mine. *cf.* mine-shaft (*q.v.*).
- mine-shaft:** vertical or near-vertical tunnel in a mine. *cf.* mine-adit (*q.v.*).
- Miocene:** geological Epoch (within the Tertiary Period); ca. 23–5 mya.
- miombo:** a vernacular name applied to trees in the genus *Brachystegia*; a type of savanna woodland in the Zambezan region where *Brachystegia* spp. are the commonest trees or one of the commonest trees.
- Mistbelt:** foothills along the eastern Great Escarpment that experience regular fogs, with vegetation comprising mainly grasslands and patches of afro-montane forest in protected valleys and ravines.
- mist-net:** rectangular net made of fine netting (usually monofilament, sometimes two-ply), hung vertically between two upright poles. Several taut, horizontal strands of stronger thread ensure that the net hangs in such a way that a series of horizontal pockets is formed. Bats or birds flying into mist-nets usually fall into a pocket and become tangled. Mist-nets are usually 2.4 m wide and from 5.5 to at least 12.8 m long. They can be set at ground-level or elevated. Mist-nets need very frequent monitoring to prevent injury and stress to entangled animals.
- mitochondrial DNA:** the small amount of DNA contained within the mitochondria of a cell.
- molar:** grinding or cutting tooth rooted in the maxilla bone or the mandible; there are usually one, two or three molar teeth in each ramus of the jaw. Together with the premolars, if present, they form the “cheekteeth”. The number and form of the molar teeth varies in different species. Not preceded by deciduous (milk) teeth (*q.v.*).
- molariform:** similar in form to a molar tooth; used to describe the form of the premolar teeth in some taxa.
- monoestrous:** Generally, having a single oestrus cycle during a single reproductive season. *cf.* polyoestrous (*q.v.*). In bats, having one litter per year; for species and/or populations described as being monoestrous, each female has one litter/year. *cf.* polyoestrous (*q.v.*).
- monogamous:** having only one mate, usually for the whole of an animal's lifetime.
- monogamy (adj. monogamous):** a mating system in which one male mates with one female. Neither sex has the opportunity of monopolizing additional members of the opposite sex. Fitness often maximized through shared parental care (Emlen & Oring 1977). *cf.* polygyny (*q.v.*).
- monophyletic:** describes a taxonomic group descended from a common ancestor that was itself a member of that taxonomic group, and including *all* the descendants of that ancestor (Groves 2001). *cf.* paraphyletic (*q.v.*); polyphyletic (*q.v.*).
- monophyly:** derivation of taxa from a common ancestor. *cf.* diphyly (*q.v.*), polyphyly (*q.v.*).
- monotocous:** normally having only one young per litter (twinning, if it occurs, is very rare and abnormal). *cf.* polytocous (*q.v.*).
- monotypy (adj. monotypic):** describes a taxon containing only one immediately subordinate taxonomic unit, e.g. a monotypic family contains only one genus; a monotypic genus contains only one species. *cf.* polytypy (*q.v.*).
- mopane:** a vernacular name applied to the tree *Colophospermum mopane*; a type of savanna woodland in the Zambezan region in which *C. mopane* is the commonest species of trees.
- Mt:** (*abbrev.*) Mount.
- mtDNA:** (*abbrev.*) mitochondrial DNA (*q.v.*).
- Mts:** (*abbrev.*) Mountains.
- muzzle:** the snout; the nose and jaws of a mammal.
- MW:** (*abbrev.*) see mastoid width.
- mya:** (*abbrev.*) millions of years ago.
- myotodont:** lower molars of bats in the family Vespertilionidae are described as myotodont when the postcrisid ridge directly connects the hypoconid cusp with the entoconid cusp, leaving the hypoconulid isolated (Figure 138). *cf.* nyctalodont (*q.v.*).
- n. d.:** (*abbrev.*) no data.

- N. P.**: (*abbrev.*) National Park.
- narial**: pertaining to the nostrils.
- neonate**: a newly born animal.
- neoparatype**: any specimen described at the same time as the neotype (*q.v.*).
- neotype**: a specimen selected as the type in cases where the primary types are definitely known to be lost or destroyed.
- nipple**: external opening of mammary gland. Nipple number and position vary according to the taxon, but are consistent within a species. Nipples arranged in pairs, one of the pair on each side of body. Nipple number (if given) is: the number and the position of the nipples on one side of the body, and the total number for both sides. For example, in golden-moles, nipple number is: 1 (abominal) + 1 (inguinal) = 4. In some shrews, nipple number is 0 (pectoral) + 2 (inguinal) = 4 (total).
- nipple-clinging**: the behaviour of neonates and unweaned young that remain semi-permanently attached to the nipples of the mother (including while she is foraging) for a period of several days to several weeks. In some species there is a gap between the two deciduous upper incisor teeth, which assists in nipple-clinging.
- nipple-dragging**: situation when a mother drags her neonates and unweaned young, firmly attached to her nipples, when she is active outside her nest. *cf.* nipple-clinging.
- NL breadth**: in bats, the maximum breadth of the noseleaf. For bats in the family Rhinolophidae = breadth of horseshoe excluding lateral leaflets if present.
- NL length**: in bats, the length of the noseleaf.
- nocturnal**: at or active in the night; when light intensity is at its lowest; between sunset and sunrise. *cf.* crepuscular (*q.v.*); diurnal (*q.v.*).
- nomadic movements**: irregular and unpredictable movements, from one locality to another, made by species living in unpredictable habitats. *cf.* localized movements (*q.v.*); migration (*q.v.*).
- nomen dubium**: when the available evidence is not sufficient to permit the identification of a species, its name is considered to be a *nomen dubium* and therefore not available for taxonomic purposes.
- nomen nudum**: a name that is not valid because, when it was originally published, the organism to which it referred was not adequately described, defined or sketched. The name is therefore invalid because it is impossible to associate it indisputably with any specific organism.
- nominate subspecies**: the subspecies that bears the name of the species to which it belongs (e.g. *Myotis bocagii bocagii*), only brought into existence by the creation of one or more other subspecies in the same species (e.g. *Myotis bocagii cupreolus*).
- North Africa**: those parts of Mauritania, Morocco, Algeria, Tunisia, Libya and Egypt that are north of the Sahara Desert.
- north-central Africa**: southern Chad and southern Sudan, west of the Nile R. and south of the Sahara. Mainly savanna habitats.
- north-west Africa**: (= Mahgreb) those parts of Mauritania, Morocco, Algeria, Tunisia and NW Libya that are north of the Sahara Desert.
- noseleaf**: fleshy outgrowth on the dorsal surface of the muzzle of bats in some families, associated with the modification of their echolocation calls.
- nulliparous**: not having given birth.
- nursery colony**: *see* maternity colony.
- nyctalodont**: lower molars of bats in the family Vespertilionidae are described as nyctalodont when the postcristid ridge connects the hypoconid cusp with the hypoconulid without reaching the entoconid cusp (Figure 138). *cf.* myotodont (*q.v.*).
- obligate**: obligatory; limited to one mode of life or action irrespective of conditions or circumstances. *cf.* facultative (*q.v.*).
- occipital condyles**: the pair of smooth, rounded processes of the occipital bone at the posterior end of the skull on either side of the occipital foramen which acts as a hinge between the head and the neck.
- occipital helmet**: backward-pointing projection of the skull, formed either when the sagittal and lambdoid crests are well developed and united, or (in absence of sagittal crest) when the lambdoid crest is well developed and backward-pointing. Sometimes abbreviated to helmet.
- occiput**: the posterior part of the skull, above the foramen magnum (*q.v.*).
- occlusal**: pertaining to the biting surface of a tooth.
- Oligocene**: geological Epoch (within the Tertiary period), ca. 38–23 mya.
- omnivore** (*adj.* **omnivorous**): an animal that eats a wide range of foods.
- orbicularis**: one of the muscles under the skin of a hedgehog, which, when contracted, causes the hedgehog to roll up into a ball.
- orbit**: bony cavity (eye-socket) in which the eye is situated.
- osmetrichia**: hairs structurally specialized for the dispersal of scent.
- outer**: furthest from the mid-line of the body.
- outer margin of ear**: in bats, the margin that is furthest from the mid-line of the body; in most species, this is also the posterior margin.
- ovulation**: the release of female gametes (ova, eggs) from the ovary.
- ovum**: the female gamete or egg cell.
- owl pellets**: waste material, normally in an egg-like shape, regurgitated by owls, which contains undigested fragments of bone, hair, feathers and scales etc. from the prey; for mammalogists, useful in determining indirectly the species of small mammals in a habitat.
- P** or **p**: (*abbrev.*) premolar tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* premolar.
- Palaearctic**: a zoogeographic region comprising temperate Europe, North Africa and the Arabian Peninsula.
- Palaeocene**: geological Epoch (within the Tertiary Period); 65–55 mya.
- palatal emargination**: the gap in the anterior of the bony palate associated with the loss or reduction of palatal branches of premaxillae. In bats, it can be closed (non-existent), shallow (barely reaching incisors), deep (reaching level of canines) or very deep (reaching level of premolars or beyond), narrow or wide, and can vary in shape (e.g. U-shaped, V-shaped, bulb-shaped) (Figure 24).
- palatal length**: the anterior–posterior length of the bony palate, taken at the mid-line (Figure 23). For *Rhinolophus* spp., data from Csorba *et al.* (2003) does not include the spike projecting from the posterior margin of the palate.

- palatal ridges:** fleshy ridges crossing the roof of the mouth from side to side.
- palatal shelf:** in hedgehogs, the bony palate of the skull; maximum width is a useful identification character; see also palate (*q.v.*)
- palate:** the roof of the mouth. The anterior part (hard palate) comprises the bony palate (formed by the premaxillae, maxillae and palatine bones), and a covering mucous membrane. The posterior part (soft palate) is composed only of muscular tissue covered by a mucous membrane.
- palpably pregnant:** describes a pregnant female whose pregnancy has been detected only by feeling the foetus(es), not by dissection. It is not possible to detect the early stages of pregnancy by palpation.
- panniculus:** in hedgehogs, one of the muscles under the skin which, when contracted, causes the hedgehog to roll up into a ball.
- papilla** (*pl. papillae, adj. papillate*): a small projection or protuberance.
- paramontane distribution:** *sensu* Koopman 1983, the geographical distribution of a species that is restricted to mountainous regions although the altitudinal range covers both lower and higher elevations.
- paraoccipital process:** narrow strut-like bone, which projects ventrally from the paraoccipital bone on the posterior part of the skull.
- parapatry** (*adj. parapatric*): the situation where two or more species have geographic ranges that are contiguous but do not overlap. This abutting may be along a line of habitat discontinuity, ecotone, or altitudinal/climatic contour, but may also arise from competitive exclusion of one (or both) by the other.
- paraphyletic:** describes a taxon containing units that have evolved from a single ancestral taxon but which do not contain all of the descendants of the most recent common ancestor.
- parastyle:** in shrews, small cusp on outer anterior margin (and labial to the paracone) of a molar tooth.
- paratype:** a specimen collected at the same time and place as the holotype (*q.v.*) and designated by the original authority as such. There may be one or more paratypes.
- parietal:** one of the pair of bones forming the vault of the braincase, situated between the frontal and the occipital bones.
- parous:** having given birth.
- particoloured:** partly of one colour and partly of another colour (as opposed to uniformly coloured).
- partim:** in taxonomy, used in context of taxon names and synonyms to indicate that not all material that has been referred to the name is currently considered to belong to that name. e.g. *auritus* (*partim*) is listed as a synonym of *Plecotus christii* because only some of the specimens that were earlier identified as *Plecotus auritus* are now considered to represent *P. christii*.
- parturition:** the act of giving birth.
- patagium:** flight membrane.
- pectoral:** pertaining to or situated on the chest.
- pelage:** the hairy, woolly or furry covering of the body in mammals. The pelage variously consists of hairs, guard hairs and underfur according to the species.
- perch-hunting:** in bats, any foraging behaviour in which the bat hangs from a perch while searching for its prey and then returns to the perch to eat and/or to resume searching. Includes fly-catching (*q.v.*) and some types of gleaning (*q.v.*).
- phalanx** (*pl. phalanges*): one of the bones in a finger.
- phenotype:** the visible characters of an individual resulting from the interaction between the genotype (*q.v.*) and the environment.
- philopatry:** the tendency to remain in or consistently return to the place where one was born.
- phylogenetics:** pertaining to the line of descent of a taxon; a method of classification which attempts to show the evolutionary relatedness of organisms.
- phylogeny** (*adj. phylogenetic*): the evolutionary history and line of descent of a species or higher taxonomic unit.
- phytophilic:** loving or thriving with plants; inhabiting domiciles or day-roosts in foliage, on tree trunks, in hollow trees, under bark etc. *cf.* anthropophilic (*q.v.*); lithophilic (*q.v.*).
- piloerection:** the erection of hairs which occurs as a means of conserving heat (*see* temperature regulation) and, in some mammals, as a threat display.
- pilosity:** in shrews, refers to the pale well-spaced long hairs on the tail of some species of shrews (mainly *Crocidura*); expressed as a percentage of length of the tail with long hairs (measured from base of tail to tip) to the total tail length. e.g. 0% = no long hairs, 30% = long hairs on basal 30% of tail, 100% = long hairs over whole length of tail, etc.
- pinna** (*pl. pinnae*): the external (outer) ear.
- placental scars:** scars on the inner surface of the uterus of a mammal; the site where a placenta was attached during pregnancy. The number of placental scars can give an indication of the number of litters that a female has had (when the average number of young/litter is known).
- plagiopatagium:** in bats, that part of the wing-membrane posterior to the forearm, i.e. between the body and the fifth finger.
- plantar:** of the sole of the foot.
- Pleistocene:** geological Epoch (within the Quaternary Period); ca. 1.7 mya to 10,000 year ago.
- plesiomorphy** (*adj. plesiomorphic*): in cladistics (*q.v.*), describes a pre-existing character state across a wide taxonomic grouping. Sharing of that state (symplesiomorphy [*q.v.*]) amongst a subset of taxa within the wider grouping is not indicative of monophyly (*q.v.*). *cf.* apomorphy (*q.v.*).
- Pliocene:** geological epoch (within the Tertiary period), ca. 2–5 mya.
- pollex:** digit 1 ('thumb') of forefoot ('hand').
- polygyny** (*adj. polygynous*): a mating system in which one male mates with several females. *See* resource-defence polygyny; female-defence polygyny. *cf.* monogamy (*q.v.*).
- polymorphism** (*adj. polymorphic*): the existence, within a species or population, of individuals having different forms (colour, size, shape etc.).
- polyoestrus:** generally, having a succession of oestrus cycles during a single reproductive season, *cf.* monoestrous (*q.v.*). In bats, having two or more litters/year; for species and/or populations that are described as polyoestrous, each female has two or more litters/year. *cf.* monoestrous (*q.v.*).
- polyphyletic:** describes a taxon derived from two or more ancestral sources; not of a single, immediate line of descent (Mayr *et al.* 1953). *cf.* monophyletic (*q.v.*).
- polyphyly:** derivation of a taxon from two or more ancestral sources. *cf.* monophyly (*q.v.*).

polytocus: normally or often having more than one young per litter. *cf.* monotocus (*q.v.*).

polytypy (*adj.* **polytypic**): a taxon that has several taxa in the next lower taxonomic category, e.g. a polytypic family contains two or more genera, a polytypic genus has two or more species. *cf.* monotypy (*q.v.*).

postauricular: behind the external ear (pinna).

postcalcareal lobe: a small lobe, situated behind the calcar of some bats, that forms a small projection of the interfemoral membrane (Figure 22).

postcristid ridge: in bats, the most posterior ridge (commissure) on a lower molar tooth (Figure 138).

postorbital: behind (posterior to) the orbit.

postorbital process: in bats, the bony projection arising from upper rim of orbit and projecting outwards and downwards around the posterior of the orbit (Figure 23); described as present, absent, long, slender and conspicuous, or concealed as result of merging with supraorbital ridge.

postpartum oestrus: an oestrus cycle immediately after (or very soon after) parturition and while lactating.

predicted mean maximum urine concentration: in microbats, an indicator of the urine-concentrating capacity of the kidney predicted from the ratio of the thickness of the renal cortex to the thickness of the medulla. Known range ca. 2300–5000 mOsmol/kg, therefore 2300–2840 is comparatively very low, 2841–3380 is low, 3381–3920 is medium, 3921–4460 is high and 4461–5000 mOsmol/kg is very high.

premaxilla (*pl.* **premaxillae**): one of a pair of bones at the anterior end of the skull, which bears the incisor teeth. In bats, comprised of a pair of nasal branches that form the anterior end of the rostrum, and a pair of palatal branches that carry the incisors and form the anterior end of the bony palate. Either or both branches may be present or absent, well-developed or reduced, independent or fused with other bones.

premolar: tooth (or teeth) on the maxilla bone; situated immediately anterior to the molar teeth; usually preceded in time by deciduous (milk) teeth. Number of premolars ranges from none to four according to species. Variable in structure and function.

preorbital: anterior to the eye.

procumbent: in context of teeth of bats, angled forward.

promiscuity: a mating system in which each male mates with several females and each female mates with several males.

protocone: The main inner (lingual) cusp of an upper molar tooth.

protopatagium: in bats, that part of wing-membrane anterior to the forearm (Figure 22).

proximal: nearest to the body or to the mid-line of the body; nearest to the point of attachment. *cf.* distal (*q.v.*).

pterygoid: one of a pair of cranial bones forming part of the roof of the mouth.

pterygoid process: one of a pair of narrow, ventrally projecting processes of the pterygoid bones situated immediately posterior to the bony palate and forming the walls of the mesopterygoid fossa (*q.v.*).

pubic nipples: pair of nipples found in the pubic region of bats in the families Rhinolophidae, Hipposideridae and Megadermatidae (and extralimitally Craseonycteridae), which provide holdfasts for the young and may have at least some lacteal function in many

species (Simmons 1993). Also known as false nipples, abdominal nipples and pelvic nipples.

pyriform: pear-shaped.

Quaternary Period: period within the Cenozoic Era; 2 mya to today, comprising two epochs: the Pleistocene and Holocene (Recent) (*q.v.*).

R.: (*abbrev.*) River.

radio-metacarpal pouch: in bats, a small flap of skin stretching between the forearm and the metacarpal of the fifth finger, ventrally to the wing-membrane, and forming a small, shallow pouch (Figure 84c).

radius: one of the two bones of the lower forelimb (the forearm of bats) between the humerus (upper arm) and the wrist.

ramus: one half (left or right) of the lower jaw or mandible.

range length: distance between the most distant captures (by live-trapping) of an individual; a rough method of assessing home-range (*q.v.*).

Recent: see Holocene (*q.v.*).

relatively: used in the context of describing the size of one character relative to the size of a different character in the same species. Usually expressed as a percentage. e.g. Tail 80–90% of HB. *cf.* comparatively (*q.v.*).

relict forest: a forest that persists where local conditions are favourable after the disappearance of forest from the surrounding area as a result of climate change or human activity. Relict forests include those at the base of inselbergs, which are watered by rainwater running off the inselberg, and forests growing in graveyards and sacred sites that are protected. Sometimes known as forest islands.

relict population: one that persists where local conditions are favourable after the extinction of the species from at least part of its former range.

reproductive capacity: number of young produced by a female during the breeding season.

reproductive chronology: the timing and duration of events, such as spermatogenesis, copulation, ovulation, gestation, parturition, lactation and reproductive inactivity, throughout the year.

resource-defence polygyny: a mating system in which a male controls access to several females indirectly, by monopolizing critical resources (Emlen & Oring 1977).

retarded embryonic development: a means of lengthening the interval between copulation and parturition so that both events can occur in the most optimal seasons. The implanted embryo enters a period of retarded (slowed) growth, which may last 4–8 months, after which development proceeds normally.

reticulation: having a net-like pattern.

rhinarium: area of naked moist skin surrounding the nostrils.

ridge (= commissure): in teeth, a ridge connecting two cusps.

Rift Valley: deep valley extending from the Red Sea through Ethiopia and East Africa to Malawi; formed ca. 12 mya by subsidence of the valley floor and uplifting of the edges to form mountains and highlands. Four parts: (1) Ethiopian Rift Valley dividing the Ethiopian plateau into two parts; (2) Albertine Rift Valley (Western Rift Valley) in Uganda, E DR Congo and W Tanzania; (3) Gregorian Rift Valley (Eastern Rift Valley) in N Kenya, C Kenya and N Tanzania; (4) Malawian Rift Valley – the extension of the Albertine Rift Valley in Malawi. The Rift Valleys are noted for their many deep and beautiful lakes.

- riparian:** growing on or living on the banks of streams or rivers.
- riverine forest:** forest growing along the banks of a river or stream where conditions are moister than in the surrounding area. Sometimes referred to as 'fringing forest'.
- Robertsonian fusion:** a chromosomal event involving the apparent fusion of non-homologous single armed (telocentric *q.v.*) chromosomes to form a bi-armed (metacentric *q.v.* or submetacentric *q.v.*) chromosome. Modern studies have revealed that all chromosomes have two arms, even if the smaller one is not detectable by light microscopy. Consequently, the term Robertsonian translocation is becoming more commonly used than Robertsonian fusion.
- roost-fidelity:** in bats, returning to roost at the same place, day after day.
- rostral:** pertaining to the rostrum.
- rostrum:** that portion of the skull anterior to the front line of the orbits and supporting the upper part of the muzzle, comprised of the nasals, premaxillae and maxillae bones.
- r-selection:** selection for characteristics suitable in unstable fluctuating environments (rapid development of young, large litter-size, relatively short time to maturity, relatively short life-span) *cf.* K-selection (*q.v.*).
- ruff (= collar):** in bats, a wide band of hairs, which differ in colour, length and/or texture from other hairs, extending from the shoulders across the throat and upper chest of some bats (Figure 34d), in some species, the ruffs arise from glandular skin and are sometimes stained by glandular secretions.
- rupicolous:** rock-living.
- s.u.:** (*abbrev.*) (*Lat. sans unguis* = without claw) sometimes added as a suffix to the hindfoot measurement to emphasize that HF has been measured without the claw. However, since this is the standard method of measurement, most authors write 'HF', not 'HF s.u.'. *cf.* c.u. (*q.v.*).
- sagittal crest:** longitudinal crest of raised bone on the mid-dorsal line of the cranium.
- scansorial:** climbs or scrambles over logs and in low vegetation close to the ground. *cf.* terrestrial (*q.v.*); arboreal (*q.v.*).
- sclerophyllous:** describes vegetation having hard leaves that are resistant to drought.
- scrotal:** pertaining to, or within, the scrotum (*q.v.*).
- scrotum:** an external sac containing the testes and epididymides in male mammals.
- scuttling:** rapid cursorial locomotion over the ground (or similar surfaces) in which the limbs move quickly; for bats and other small mammals, scuttling is quadrupedal.
- sella:** the transverse structure arising immediately above the horseshoe component of the noseleaf of bats in the family Rhinolophidae and sometimes overhanging the top of the horseshoe (Figure 56). The shape of the front face of the sella viewed from the front (Figure 60), and the pilosity of the front face, are diagnostic characters.
- semi-lunate:** half-moon shaped.
- Senegambia:** Senegal and Gambia.
- sensu:** (*Lat.*) in the sense of.
- sensu lato:** (*Lat.*) in a broad sense.
- sensu stricto:** (*Lat.*) in a strict sense.
- septum:** a dividing wall separating two cavities.
- sex ratio:** the number of males to the number of females, usually expressed as a proportion to one male, e.g. 1 : 1 (equal numbers of males and females), 1 : 0.5 (= twice as many males as females), 1 : 2 (= twice as many females as males).
- sexual dimorphism:** observable (phenotypic) difference(s) (e.g. in colour, size or form) between the males and females of a species or higher taxon.
- sibling species:** pairs or groups of true species that are reproductively isolated, but genetically closely related and so similar in appearance that they are difficult to separate solely on the basis of morphological characters.
- side-stripe:** longitudinal stripe(s) of contrasting colour on each flank, usually from shoulder to rump or upper part of hindlimbs. May be bordered by additional side-stripe above and below.
- singleton:** a neonate that is born singly as opposed to being one of a larger litter.
- sister species:** species that are thought to have arisen from a single dichotomous splitting event.
- soft-bodied:** describes insects (e.g. eaten by bats) that have soft cuticles (e.g. moths, flies). *cf.* hard-shelled (*q.v.*).
- south-central Africa:** Angola, SE DR Congo, Zambia and Malawi (but only west of L. Malawi and the Shire R. Valley).
- southern Africa:** South of the Cunene and Zambezi rivers (i.e. Namibia, Botswana, Zimbabwe, southern Mozambique and South Africa (after Smithers 1983).
- spatulate:** like a spatula, i.e. narrow at the base but wider, flat and parallel-sided distally.
- sperm storage:** storage of sperm in the cauda epididymides (*q.v.*) of males for some time before copulation, or in the reproductive tract of females for an extended period before ovulation takes place. A type of reproductive delay that, in females, lengthens the length of gestation (*q.v.*).
- sperm:** any male gamete; the male cell that fuses with a female gamete (ovum, egg cell) to produce a fertilized egg or zygote from which an embryo will develop.
- spermatogenesis:** the formation of sperm in the testes.
- spoon-hairs (= spatulate hairs):** short, spoon-shaped, bristle-like hairs with tips flattened and slightly curved; e.g. on lips and feet of some bats in the family Molossidae.
- stall-and-twist turning:** in bats, a method of turning during flight to minimize the radius of turn. Because radius of turn is proportional to speed, the bat swoops upwards until its speed is near zero before making the adjustments to the form of its flight membranes, which cause it to roll and turn. *cf.* banking (*q.v.*).
- sub, sub-:** prefix meaning under, signifying beneath or ventral to (as in anatomical features) or south of (as in sub-Saharan); less than (as in subsonic); not quite, nearly, almost, somewhat (as in subequal, subtriangular). In taxonomy, indicates a group just below the status of the taxa immediately following it (e.g. a genus may contain two or more subgenera).
- subauricular:** below the ear.
- subcaudal:** below the tail.
- submetacentric:** describes a chromosome with the centromere (*q.v.*) somewhat nearer one end than the other, so there are two arms of somewhat unequal length (ratio 1 : 1.2–1.9). *cf.* metacentric (*q.v.*); subtelocentric (*q.v.*).

- subspecies:** a geographically localized and isolated subdivision of a species, which differs genetically, morphologically and taxonomically from other subdivisions of the species.
- subtelocentric:** describes a chromosome with the centromere (*q.v.*) much nearer one end than the other, so there are two arms of very unequal length (ratio 1 : >2).
- subterminal:** just below the end or tip.
- subterranean:** living permanently below the ground; subterranean mammals show many adaptations for life underground, e.g. short limbs, thickset shoulder blades and forelimbs, reduced eyes, reduced ability to see, reduction (or absence) of ear pinnae, large extra-buccal incisors, sensory hairs over all the body, feet fringed with hairs, extensive subterranean burrows, etc. (e.g. species of Chrysochloridae). *cf.* fossorial (*q.v.*).
- suckling:** the act of a mother giving milk directly from her breast (mammary glands) to her young. Mothers suckle; their young suck.
- supraoccipital crest:** ridge of bone, orientated transversely across the back of the skull, at the junction of the parietal and/or supraoccipital bones and the occipital bone. Sometimes referred to as the lambdoid crest.
- supraorbital:** above (dorsal to) the orbit.
- supraorbital ridge:** ridge of bone along upper rim of orbit (eye-socket); can be well developed, low or absent.
- sympatry** (*adj.* **sympatric**): the situation where populations of two or more different species have overlapping geographic ranges; refers also to populations of two or more species whose geographic ranges are partly or wholly overlapping. They may or may not interact. *cf.* allopatry (*q.v.*); syntopy (*q.v.*).
- symplesiomorphy:** a primitive or ancestral character shared by two or more groups, which is inherited from ancestors older than the last common ancestor.
- synanthropic:** associated with humans and/or their houses and other buildings.
- synapomorphy** (*adj.* **synapomorphic**): situation in which a homologous character is present in two or more taxa and is thought to have originated in their most recent common ancestor. *See also* apomorphy.
- synonym:** one or more of different names for the same taxonomic unit. A synonym may be a 'senior synonym' (the oldest name), or a 'junior synonym' (a more recent name) that is no longer considered as valid. May be used to refer to all names that have been associated, at some time in the past, with the taxonomic unit as currently understood.
- syntopy** (*adj.* **syntopic**): describes the situation where two or more species use the same or similar habitats and activity times. They may or may not interact. *cf.* allopatry (*q.v.*); sympatry (*q.v.*).
- syntype:** any specimen, or one of a series of specimens, used to designate a species when a holotype (*q.v.*) and paratype(s) (*q.v.*) have either not been selected, or have been lost or destroyed.
- systematics:** the science of arranging organisms in a way that reflects their evolutionary relationships; such relationships may be expressed as a phylogeny (*q.v.*). Often defined (somewhat incorrectly) as a synonym of taxonomy (*q.v.*).
- t (= tubercle):** (*abbrev.*) as used to describe and number the cusps on premolar and molar teeth, e.g. t1, t3, t5.
- T:** (*abbrev.*) length of tail, measured from anterior of the first caudal vertebra to the posterior end of the last caudal vertebra (excluding any tufts, bristles etc. at tip of tail).
- T_a:** (*abbrev.*) ambient temperature; the temperature in which an animal is living. *cf.* T_b (*q.v.*).
- talonid:** heel at the posterior end of a lower molar tooth.
- tapetum lucidum:** light-reflecting layer behind or in the retina of the eyes of some vertebrates which reflects light back through the retina thereby increasing the sensitivity of the eye to dim light.
- taxon** (*pl.* **taxa**): any defined unit (e.g. family, genus, species, subspecies) in the classification of organisms.
- taxonomy:** the science of biological nomenclature; the study of the rules, principles and practice of naming and classifying species and other taxa. Sometimes considered as an integral part (and near synonym) of systematics (*q.v.*).
- T_b:** (*abbrev.*) body temperature; the temperature of the core (central) part of an animal. *cf.* T_a (*q.v.*).
- telocentric:** describes a chromosome that appears to have a terminal centromere (*q.v.*) and therefore only one arm. Modern studies have revealed that all chromosomes have two arms but the smaller arm of telocentric chromosomes is not visible under a light microscope.
- Tenebrionidae:** a family of beetles within the Order Coleoptera.
- termitarium** (*pl.* **termitaria**): a place where termites (Insecta: Isopoda) live. Often a large mound of modified hard soil. The shape and size of a termitarium is unique to each species of termite.
- terrestrial:** living on the ground. *cf.* arboreal (*q.v.*); scansorial (*q.v.*).
- territory:** an area defended by an individual against certain other members of the species, usually by overt aggression or advertisement; territory is marked by the urine, faeces or glandular secretions of the territory's owner. *cf.* home-range (*q.v.*).
- Tertiary Period:** geological period, 65–2 mya, comprising five epochs: Palaeocene, Eocene, Oligocene, Miocene and Pliocene (*q.v.*); followed by the Quaternary Period (*q.v.*).
- testes:** the male gonads, or testicles, in which spermatozoa are formed and in which the male hormone is produced.
- thermoneutral zone:** the range of body temperatures within which an animal does not have to increase its metabolic rate to increase T_b (*q.v.*) (when T_a (*q.v.*) is low) and reduce T_b (when T_a is high).
- thermoregulation:** regulation of body temperature, either by metabolic or behavioural means (or both simultaneously) so that T_b (*q.v.*) is kept more or less constant.
- thoracic:** pertaining to, or situated upon, the chest.
- through-put time:** time taken for food to pass through the digestive tract.
- Tib:** (*abbrev.*) in bats, the length of the hindleg from the knee to the distal end of ankle, usually measured from top of knee to base of ankle when both knee and ankle are flexed (bent).
- tibia** (*pl.* **tibiae**): one of the two bones forming the lower leg (the shin bone); part of hindlimb between knee and ankle.
- tip-shape:** in bats, refers to the length, area and pointedness of the hand-wing (between fingers 2 and 5) relative to the arm-wing (between the body, hindlimb and fifth finger) (see Norberg & Rayner 1987).
- TL:** (*abbrev.*) total length from tip of snout to posterior end of tail. Equivalent to the head and body length and tail length added together. *See also* HB (*q.v.*) and T (*q.v.*).

- toothrow:** Generally, the row of teeth from the most anterior incisor tooth to the most posterior molar. In bats, the row of teeth from the canine to the most posterior molar; also the line passing through the middle of the majority of these teeth (in occlusal view) indicating their alignment (used as reference line to determine if a tooth has become displaced to one side).
- topotype:** any specimen from the type locality (*q.v.*), i.e. the same locality as that from which the holotype (*q.v.*) was taken.
- topotypical:** pertaining to the type locality (e.g. a topotypical population is one found at the type locality).
- torpor** (*adj. torpid*): a state in which there is a (usually short-term) reduction of metabolic rate and a lowering of T_b (*q.v.*) when T_a (*q.v.*) declines; arousal from torpor occurs when T_a increases and without high energy costs to the individual. Torpor is associated with a state of inactivity and reduced responsiveness to stimuli. Torpor lasts for only short periods of time (hours or days) (*cf.* hibernation).
- Tr:** (*abbrev.*) in bats, length of tragus, usually from tip to junction of posterior margin with the ear. Different methods and effects of preservation contribute to the wide ranges given for some species.
- tragus:** a cartilaginous structure, usually small, projecting from the inner side of the external ear just anterior to the auditory meatus (*q.v.*). In bats, its shape and relative size is often of diagnostic importance.
- transverse:** in a direction across the body from side to side. *cf.* longitudinal (*q.v.*)
- Triassic Period:** period (within the Mesozoic Era); 248–208 mya. The first mammals appeared in this period.
- tricuspid:** having three points or cusps (particularly of teeth).
- tubercle:** a small rounded protuberance, e.g. a cusp of a tooth.
- tympanate:** having a tympanic membrane (e.g. ear drum) as a component of an organ of hearing.
- tympanic bulla** (*pl. tympanic bullae*): one of a pair of usually rounded bony capsules, on underside of skull (one on each side), housing structures of the middle and inner ear in many mammals. Also called auditory bulla (*q.v.*).
- type description:** the original description of a species; the original description of the holotype (and paratype[s] if included).
- type locality:** the locality from which a holotype (*q.v.*), lectotype (*q.v.*) or neotype (*q.v.*) was collected. Also called topotypical locality.
- type series:** the holotype and all specimens collected at the same place and time and used, together with the holotype, to describe a new species.
- type species:** usually the species that was the first to be described under the name of a new genus. Not all genera had a designated type species when they were first created; in such cases, other rules determine which species will be the type species.
- type specimen:** *see* holotype.
- underfur:** dense and often woolly layer of the pelage, situated close to the skin and below the soft hairs and guard hairs; usually short and present in those species that experience lower T_a .
- unicuspid:** having one cusp or point (particularly of teeth).
- urine concentration:** *see* predicted mean maximum urine concentration.
- vagrant:** an individual that has been found well outside the normal geographic range of its species, e.g. a bat or bird that has been wind-borne, or an animal that has been transported as a stowaway on a ship, to a distant locality.
- vascular foramen:** one of a pair of small foramina on the dorsal surface of the cranium (present in some genera of shrews).
- vascularized:** infiltrated with capillaries.
- vasoconstriction:** constriction of the capillaries of the blood system near the surface of the skin in order to reduce the rate of heat loss through the skin; a mechanism used by many mammals to conserve heat when T_a (*q.v.*) is low. *cf.* vasodilation (*q.v.*).
- vasodilation:** the dilation (or opening) of the capillaries of the blood system near the surface of the skin in order to increase the rate of heat loss through the skin; a mechanism used by many mammals to cool themselves when T_a (*q.v.*) is high. *cf.* vasoconstriction (*q.v.*).
- veld:** Africans word, used mainly by southern African biologists, to refer to a wide variety of grassland vegetation types typically used for grazing. *See also* bushveld, highveld, lowveld.
- vertebra** (*pl. vertebrae*): any of the bones that make up the backbone.
- vestigial:** small and imperfectly developed; a structure having a smaller and more simple form than the corresponding structure in an ancestral species.
- vibrissa** (*pl. vibrissae*): long stiff hairs on the face, especially around nostrils and lips; often associated with the perception of tactile sensation; 'whiskers'.
- vlei:** southern African term for a marsh or swamp, either permanent or seasonal.
- volant:** able to fly.
- wadi:** a desert valley, usually dry at the surface except after heavy rainfall.
- water turnover:** the rate at which water (fluids) is utilized and replaced in the body per unit time (normally expressed as ml/kg body weight/day); the amount of water an animal processes through its body each day. Water turnover is related to water availability, the urine concentrating ability of the kidney, amount of protein in the diet and T_a (*q.v.*). Water turnover rates are characteristically low in arid-adapted mammals when compared with non arid-adapted mammals.
- West Africa:** ca. south of 18°N from Senegal to the Sanaga R. in Cameroon, and Bioko I. (Equatorial Guinea) (Rosevear 1965).
- wing-loading:** in bats, the mass of the bat divided by its wing-area. For more details, and alternative methods of calculating wing-loading, *see* text, order Chiroptera.
- wingspan (WS):** in bats, the distance from wing-tip to wing-tip. Can be measured in several ways (*see* text, order Chiroptera).
- wrinkle:** in upper lips of some bats in the family Molossidae, a vertical ridge flanked by grooves; usually supporting spoon-hairs.
- WS:** (*abbrev.*) *see* wingspan.
- WT:** (*abbrev.*) weight of an individual, usually expressed in grams (g) or kilograms (kg).
- ZW:** (*abbrev.*) *see* zygomatic width.
- zygomatic arch:** one of a pair of cheekbones, formed of the maxillary process anteriorly, jugal bone medially and squamosal bone posteriorly. Ranges from massive, broad, widely flared and bony, to frail, slender and cartilaginous. When present, provides protection to the eyes and orbits. Also called zygoma.
- zygomatic width (ZW):** greatest width between the outer aspect of one zygomatic arch to the equivalent position on the opposite zygomatic arch (Figure 23). *See also* GWS.

Series Acknowledgements

Jonathan Kingdon, David Happold, Thomas Butynski,

Michael Hoffmann, Meredith Happold and Jan Kalina

The editors wish to record their thanks to all the authors who have contributed to *Mammals of Africa* for their expert work and for their patience over the very protracted period that these volumes have taken to materialize. We also thank the numerous reviewers who have read and commented on earlier drafts of this work.

We are also grateful for the generosity of our sponsoring patrons, whose names are recorded on our title pages, who have made the publication of these volumes possible.

Special thanks are due to Andy Richford, the Publishing Editor at Academic Press, who initiated and supported our work on *Mammals of Africa*, from its inception up to the point where Bloomsbury Publishing assumed responsibility, and to Nigel Redman (Head of Natural History at Bloomsbury), David and Namrita Price-Goodfellow at D & N Publishing, and the whole production team who have brought this work to fruition. We also acknowledge, with thanks, Elaine Leek who copy-edited every volume. We are grateful to Chuck Crumly, formerly of Academic Press and now the University of California Press, for being our active advocate during difficult times.

We have benefited from the knowledge and assistance of scholars and staff at numerous museums, universities and other institutions all over the world. More detailed and personal acknowledgements follow from the editors of each volume.

The editors are also grateful to the coordinating team of the Global Mammal Assessment, an initiative of the International Union for Conservation of Nature (IUCN), which organized a series of workshops to review the taxonomy and current distribution maps for many species of African mammals. These workshops were hosted by the Zoological Society of London, Disney's Animal Kingdom, the Owston's Palm Civet Conservation Programme, and the Wildlife Conservation Research Unit at the University of Oxford; additionally, IUCN conducted a review of the maps for the large mammals by the Specialist Groups of the Species Survival Commission. We owe a particular word of thanks to all the staff and personnel who made these workshops possible, and to the participants who attended and provided their time and expertise to this important initiative. We also thank IUCN for permission to use data from the *IUCN Red List of Threatened Species*.

Acknowledgements for Volume V

It was more than a decade ago (mid-2000) that the first authors were contacted to write profiles for Volume V. As readers of earlier volumes will know (and certainly those intimately involved in this project), *Mammals of Africa* suffered a rather tumultuous period in its latter stages, but tenacity wins out, and we are immensely grateful to all those who have so faithfully supported this project over the years.

We reserve our greatest thanks to the 86 authors who contributed their valuable time and deep experience with Africa's mammals to write the many profiles contained within these pages. Authors not only endured the countless edits and rewrites of profiles, but also responded favourably to requests to help keep their profiles updated during the long gestation period. Of course, as noted elsewhere, circumstances have meant that we have not been entirely successful at ensuring that the content of *Mammals of Africa* is absolutely current, but we likewise feel encouraged that we have managed to keep the text reasonably up-to-date.

We would be remiss not to extend a few words of thanks to several authors who played a key role in advising on their taxonomic groups (including systematics), suggesting authors, and writing and reviewing profiles, in particular: Claudio Sillero-Zubiri and David Macdonald (Canidae); Mark Taylor (Herpestidae); and Philippe Gaubert (Viverridae). Lars Werdelin kindly reviewed the fossil sections of many of the family profiles, and provided valuable taxonomic advice, as did Olaf Bininda-Emonds, João Crawford-Cabral, Philippe Gaubert, Corey Goldman, Colin Groves, the late Peter Grubb, and Mieczysław Wolsan. We fondly remember the late Harry Van Rompaey, who not only authored many small carnivore profiles (with Marc Colyn), but reviewed all of the viverrid and herpestid profiles, and provided critical and valuable taxonomic advice throughout the project on small carnivore systematics. Volume V would be much the poorer were it not for Harry's knowledge and insightful commentaries. Sadly, Harry passed away in February 2007. It is an honour that these pages include his final contributions, some of them never before published. Besides Harry, *Mammals of Africa* also saw the passing of Huw Griffiths, early in the life of the project in 2002; the profile on *Mustela putorius* (written with Fabrice Cuzin) represents Huw's final published work. We hope that this volume serves as a fitting tribute to both Harry and to Huw.

We would like to express our thanks and gratitude to the following people who kindly offered their time and expertise to help review species or higher-level profiles (or parts thereof), or who made available published or unpublished information to authors or editors (apologizing in advance to anyone whose name is inadvertently omitted or misspelled). The contributions, insights, advice and critiques of those listed below contributed immensely to improving the content and accuracy of individual profiles: Menahem Abbadi, Alexei V. Abramov, Karl Ammann, Edward Andama, Jeremy Anderson,

Mark Anderson, Francesco Angelici, John Arnould, Anagaw Atickem, Robert Atkinson, Nico Avenant, Ted Bailey, Carolyn Baker, Guy Balme, Zoe Balmforth, Amanda Barrett, Paul Bates, Hans Bauer, Karen L. Mammals of Africa:

An Introduction and Guide

David Happold, Michael Hoffmann, Thomas Butynski and Jonathan Kingdon

Mammals of Africa is a series of six volumes that describes, in detail, every extant species of African land mammal that was recognized at the time the profiles were written (Table 1). This is the first time that such an extensive coverage has been attempted; all previous books and field guides have either been regional in coverage, or have described a selection of mammal species – usually the larger species. These volumes demonstrate the diversity of Africa's mammals, summarize what is known about the distribution, ecology, behaviour and conservation status of each species, and serve as a guide to identification.

Africa has changed greatly in recent decades because of increases in human populations, exploitation of natural resources, agricultural development and urban expansion. Throughout the continent, extensive areas of forest have been destroyed and much of the forest that remains is degraded and fragmented. Savanna habitats have been altered by felling of trees and development for agriculture. Many of the drier areas are threatened with desertification. As a result, the abundance and geographic ranges of many species of mammals have declined – some marginally, some catastrophically, some to extinction. Hence, it seems appropriate that our knowledge of each

species is recorded now, on a pan-African basis, because the next few decades will see even more human-induced changes. How such changes will affect each mammalian species is uncertain, but this series of volumes will act as a baseline for assessing future change.

The study of African mammals has taken several stages. During the era of European exploration and colonization, the scientific study of African mammals was largely descriptive. Specimens that were sent to museums were described and named. As more specimens became available, and from different parts of the Continent, there was increasing interest in distribution and abundance, and in the ecological and behavioural attributes of species and communities. At first, it was the largest and most easily observed species that were the focus of most studies, but as new methodologies and equipment became available, the smaller and more cryptic and secretive species became better known. Many species were studied because of their suspected role in diseases of humans and livestock, and because they were proven or potential 'pests' in agricultural systems. During the past decade or so, there has been greater emphasis on the genetic and molecular characteristics of species. All these studies have produced a wealth of information, especially during the past 40 years or so. These volumes are not only a distillation of the huge literature that now exists on African mammals, but also of much unpublished information.

Readers will notice that there is a huge discrepancy among species in the amount of information available. Some species have been studied extensively for many years, especially the so-called 'game species', some species of primates and a few species that are widespread and/or easily observed. In contrast, other species are known only by one or a few specimens, and almost nothing is known about them. Likewise, some areas and countries have been well studied, while other areas and countries have been neglected. During the preparation of these volumes, the editors have often been surprised by the wealth of information about some species when little was anticipated, and by the paucity of information about others, some of which were assumed to be 'well known'. In addition to presenting information that is based on sound scientific evidence, the aims of these volumes are to point out where there are gaps in knowledge and to correct inaccurate information that has become embedded in the literature. For most taxa, the detail provided in the species profiles allows accurate identification.

Mammals of Africa comprises six volumes (Table 2). The volumes consist mainly of species profiles – each profile being a detailed

Table 1. The mammals of Africa.

| Order | Number of families | Number of genera | Number of species |
|-----------------|--------------------|------------------|-------------------------|
| Hyracoidea | 1 | 3 | 5 |
| Proboscidea | 1 | 1 | 2 |
| Sirenia | 2 | 2 | 2 |

Table 2. The six volumes of *Mammals of Africa*.

| Volume | Contents | Number of species | Editors |
|--------|--|-------------------|--|
| I | Introductory chapters. Afrotheria (Hyraxes, Elephants, Dugong, Manatee, Otter-shrews, Golden-moles, Sengis and Aardvark) | 49 | Jonathan Kingdon, David C. D. Happold, Michael Hoffmann, Thomas M. Butynski, Meredith Happold and Jan Kalina |
| II | Primates | 93 | Thomas M. Butynski, Jonathan Kingdon and Jan Kalina |
| III | Rodents, Hares and Rabbits | 408 | David C. D. Happold |
| IV | Hedgehogs, Shrews and Bats | 380 | Meredith Happold and David C. D. Happold |
| V | Carnivores, Pangolins, Equids and Rhinoceroses | 93 | Jonathan Kingdon and Michael Hoffmann |
| VI | Pigs, Hippopotamuses, Chevrotain, Giraffes, Deer and Bovids | 93 | Jonathan Kingdon and Michael Hoffmann |

account of the species. They have been edited by six editors who distributed their work according to the orders with which they were most familiar. Each editor chose authors who had extensive knowledge of the species (or higher taxon) and, preferably, had experience with the species in the field. Each volume follows the same general format with respect to arrangement, subheadings and contents. Because *Mammals of Africa* has contributions from 356 authors (each with a different background and speciality), and each volume was edited by one or more editors (each with a different perspective), it has not been possible or even desirable to ensure exact consistency throughout. Species profiles are not intended to be exhaustive literature reviews, partly for reasons of space. None the less, they are written and edited to be as comprehensive as possible, and to lead the reader to the most important literature for each species. Inevitably, not all information available could be accommodated for the better-known species, and so such profiles are a précis of available knowledge. Extensive references in the text alert the reader to more detailed information.

In addition to the species profiles, there are profiles for the higher taxa (genera, families, orders and above). At the very least, there is a profile for each order, for each family within the order, for each genus within the family, and for each species within the genus. For some orders there are additional taxonomic levels, for example, subfamilies (e.g. Mustelinae). The taxonomy used in these volumes mostly follows that presented in the third edition of *Mammal Species of the World: A Geographic and Taxonomic Reference* (Wilson & Reeder 2005), although authors have employed alternative taxonomies when there were good reasons for doing so. Species are often presented alphabetically within genera. Volume I differs from the other volumes in that it contains a number of introductory chapters about Africa and its environment, and about African mammals in general.

The continent of Africa

For the purposes of this work, 'Africa' is defined as the continent of Africa (bounded by the Mediterranean Sea, the Atlantic Ocean, the Indian Ocean, the Red Sea and the Suez Canal) and the islands on the continental shelf, which, at some time in their history, have been joined to the African continent. The largest of the 'continental islands' are Zanzibar (Unguja), Mafia and Bioko (Fernando Po). All 'oceanic islands', e.g. São Tomé, Príncipe, Annobón (Pagulu), Madagascar, Comoros, Seychelles, Mauritius, Socotra, Canaries, Madeira and Cape Verde are excluded, with the exception of Pemba, which is included because of its close proximity (ca. 50 km) to the mainland.

The names of the countries of Africa are taken from the *Times Atlas* (2005). The Republic of Congo is referred to as 'Congo' and the Democratic Republic of Congo (former Zaire) as 'DR Congo'. Smaller geographical or administrative areas within countries are rarely referred to except for Provinces in South Africa, which are used extensively in the literature. A political map of Africa, and of the Provinces of South Africa, is given (Fig. 1), as well as a list of the 47 countries together with their previous names that are used in the older literature on African mammals (Table 3).

Africa is the second largest continent in the world (after Asia), but it differs from other continents (except Australia and Antarctica) in being essentially an island. At various times in the past, Africa has been joined to other continents – a situation that has had a strong influence on the fauna and flora of the continent. Africa is a vast continent (29,000,000 km², 11,200,000 mi²) that straddles the Equator, with about two-thirds of its area in the northern hemisphere and one-third in the southern hemisphere. As a result, Africa has many varied climates (with seasons in each hemisphere being six months out of phase), many habitats (including deserts, savannas, woodlands, swamps, rivers, lakes, moist forests, monsoon forests, mountains and glaciers), and altitudes ranging from 155 m (509 ft) below sea level at L. Assal, Djibouti, in the Danakil (Afar) Depression, to 5895 m (19,341 ft) on Mt Kilimanjaro, Tanzania. Africa is comprised of 47 countries, some of which are very large (e.g. Sudan [2,506,000 km²; 967,000 mi²], Algeria [2,382,000 km², 920,000 mi²], and Democratic Republic of Congo [2,345,000 km², 905,000 mi²]), and others that are relatively small (e.g. Djibouti [23,200 km², 9,000 sq miles], Swaziland [17,400 km², 6,700 mi²] and The Gambia [11,300 km², 4,400 mi²]). The human population of each country also varies greatly, from about 346/km² in Rwanda to only about 2.5/km² in Namibia. With its great size and varied habitats, Africa supports a high biodiversity, including a large number of species of mammals. Likewise, most countries have a high diversity of mammals (especially when compared with temperate countries).

Africa may also be categorized into Biotic Zones (Fig 2.). A biotic zone is defined as an area within which there is a similar environment (primarily rainfall and temperature) and vegetation, and which differs in these respects from other Biotic Zones. Africa can be divided into 13 Biotic Zones, two of which may be divided into smaller categories. The Biotic Zones concept provides a general assessment of the environmental conditions in which a species lives, as well as providing an assessment of the geographic distribution of the species. The Rainforest Biotic Zone and the South-West Arid Biotic Zone may be divided into regions and sub-regions that reflect the different biogeographical distributions of species, each region/

Figure 1. (a) Political map of Africa; (b) provinces of South Africa; (c) altitudes and major rivers of Africa. South Sudan and Somaliland are not identified as separate countries in the text.

Table 3. The countries of Africa: names, areas and human population density.

| Country name | Area
(km ²) '000 | Area
(miles ²) '000 | Human population
'000 (2006) | People per km ² |
|--|---------------------------------|------------------------------------|---------------------------------|----------------------------|
| Algeria | 2,382 | 920.0 | 33,500 | 14.1 |
| Angola (includes Cabinda) | 1,247 | 481.0 | 15,800 | 12.7 |
| Benin * [Dahomey] | 113 | 43.0 | 8,700 | 77.0 |
| Botswana [Bechuanaland] | 582 | 225.0 | 1,800 | 3.1 |
| Burkina Faso * [Upper Volta; Burkina] | 274 | 106.0 | 13,600 | 49.6 |
| Burundi [part of Ruanda-Urundi (= part of Belgian Congo)] | 27.8 | 10.7 | 7,800 | 280.5 |
| Cameroon [includes former French Cameroon, German Cameroon and part of Eastern Nigeria] | 475 | 184.0 | 17,300 | 36.2 |
| Central African Republic # | 623 | 241.0 | 4,300 | 6.9 |
| Chad [Tchad] | 1,284 | 496.0 | 10,000 | 5.8 |
| Congo [Republic of Congo] | 342 | 132.0 | 3,700 | 10.8 |
| Côte d'Ivoire * [Ivory Coast] | 322 | 125.0 | 19,700 | 61.2 |
| Democratic Republic of Congo [Belgian Congo; Congo (Kinshasa); Zaire] | 2,345 | 905.0 | 62,700 | 26.7 |
| Djibouti [French Somaliland] | 23.2 | 9.0 | 800 | 34.5 |
| Egypt | 1,001 | 387.0 | 75,400 | 75.3 |
| Equatorial Guinea # (includes Rio Muni [Spanish Guinea] and Bioko I. [Fernando Po]) | 28.1 | 10.8 | 500 | 17.8 |
| Eritrea (formerly part of Ethiopia) | 94 | 36.0 | 4,600 | 48.9 |
| Ethiopia [Abyssinia] | 1,128 | 436.0 | 74,800 | 66.3 |
| Gabon # | 268 | 103.0 | 1,400 | 5.2 |
| The Gambia | 11.3 | 4.4 | 1,500 | 132.7 |
| Ghana [Gold Coast] | 239 | 92.0 | 22,600 | 94.6 |
| Guinea * | 246 | 95.0 | 9,800 | 39.8 |
| Guinea-Bissau [Portuguese Guinea] | 36 | 13.9 | 1,400 | 38.9 |
| Kenya | 580 | 224.0 | 34,700 | 59.8 |
| Lesotho [Basutoland] | 30.4 | 11.7 | 1,800 | 59.2 |
| Liberia | 111 | 43.0 | 3,400 | 30.6 |
| Libya | 1,760 | 679.0 | 5,900 | 3.6 |
| Malawi [Nyasaland] | 118 | 46.0 | 12,800 | 108.5 |
| Mali * | 1,240 | 479.0 | 13,900 | 11.2 |
| Mauritania * | 1,030 | 412.0 | 3,200 | 3.1 |
| Morocco [includes former Spanish Morocco and French Morocco]; (now also includes Western Sahara = former Spanish Sahara) | 447 | 172.0 | 32,100 | 71.8 |
| Mozambique [Portuguese East Africa] | 802 | 309.0 | 19,900 | 24.8 |
| Namibia [South-west Africa] | 825 | 318.0 | 2,100 | 2.5 |
| Niger * | 1,267 | 489.0 | 14,400 | 11.3 |
| Nigeria | 924 | 357.0 | 134,500 | 145.6 |
| Rwanda [part of Ruanda-Urundi (= part of Belgian Congo)] | 26.3 | 10.2 | 9,100 | 346.0 |
| Senegal * | 197 | 76.0 | 11,900 | 60.4 |
| Sierra Leone | 71.7 | 27.7 | 5,700 | 79.5 |
| Somalia* [British Somaliland and Italian Somaliland; Somali Republic] | 638 | 246.0 | 8,900 | 13.9 |
| South Africa | 1,220 | 471.0 | 47,300 | 38.7 |
| Sudan § [Anglo-Egyptian Sudan] | 2,506 | 967.0 | 41,200 | 16.4 |
| Swaziland | 17.4 | 6.7 | 1,100 | 63.2 |
| Tanzania [German East Africa; Tanganyika] (now includes Zanzibar I., Mafia I. and Pemba I.) | 945 | 365.0 | 37,900 | 40.1 |
| Togo [Togoland] | 56.8 | 21.9 | 6,300 | 110.9 |
| Tunisia | 164 | 63.0 | 10,100 | 61.6 |
| Uganda | 236 | 91.0 | 27,700 | 117.4 |
| Zambia [Northern Rhodesia] | 753 | 291.0 | 11,900 | 15.8 |
| Zimbabwe [Southern Rhodesia] | 391 | 151.0 | 13,100 | 33.5 |
| Totals/mean density | 29,448 | 11,383 | 902,600 | 56.8 |

Former names are listed in chronological order in square brackets, with the oldest name listed first. Obsolete names are listed because much of the older literature refers to past colonial entities. * = formerly part of French West Africa. # = formerly part of French Equatorial Africa. § At the time of going to press, the country of Sudan had been divided into two: the Republic of Sudan in the north, and the Republic of South Sudan in the south. * The former British Somaliland is now a self-declared state under the name of the Republic of Somaliland, but remains internationally unrecognized.

Figure 2. The biotic zones of Africa. The numbers refer to the biotic zones as described in the text (from Happold & Lock, Volume I, *Mammals of Africa*).

sub-region having a community of mammals and other animals that is different to any other. Details of the Biotic Zones of Africa, and the regions and sub-regions of the Rainforest Biotic Zone and the South-West Arid Biotic Zone, are given in Volume I of *Mammals of Africa*.

Figure 3. External features of a mammal: Common Eland *Tragelaphus oryx*.

The carnivores, pangolins, equids and rhinoceroses of Africa

This volume is devoted to the orders Carnivora (carnivores), Pholidota (pangolins) and Perissodactyla (equids and rhinoceroses). The most diverse is the carnivores (83 native species), ranging from iconic charismatic species like the Lion *Panthera leo* and African Wild Dog *Lycaon pictus* to the remarkable diversity of mongooses and genets. Carnivores show a close relationship with the pangolins (4 species) and, in turn, the carnivores and pangolins are allied with a clade that unites the perissodactyls with the cetartiodactyls (pigs, hippopotamuses, chevrotain, giraffes, deer and bovids; the subject of Volume VI). Note that introduced species are mentioned in the higher-level profiles (where relevant), but are not otherwise profiled.

At the time of going to press, genetic research has suggested that a fifth species of the genus *Canis* occurs in Africa, namely the Grey Wolf *C. lupus* (Rueness *et al.* 2011; and see Gaubert *et al.* 2012). Further brief discussion is provided under the genus profile and species profile for the Golden Jackal *Canis aureus*, but the species is otherwise not separately profiled.

As *Mammals of Africa* was being finalized, a new work by Colin Groves and the late Peter Grubb, *Ungulate Taxonomy*, was published but it has not been possible to fully consider and evaluate the conclusions and classification presented in that work.

Species profiles

Information about each species is given under a series of subheadings. The amount of information under each of these subheadings varies greatly between species; where no information is available, this is recorded as 'No information available' or words to this effect. The sequence of subheadings is as follows:

Figure 4. External features of a mammal: *Genetta* sp. (side-view and face frontal).

Scientific name (genus and species) The currently accepted name of the species.

Common names English, French and German names are given, as available. The first given English name is the preferred common name for the species; alternative names are given in parentheses for some species. Wilson & Cole (2000) list proposed common names for all the world's mammals; most of these names were also given in the third edition of *Mammal Species of the World* (Wilson & Reeder 2005). Although these works have been consulted, the names used have not always been adopted in *Mammals of Africa*. French and German names were usually provided by authors.

Scientific Citation This provides the full scientific name of the species, i.e. genus name, species name, authority name, and date of authority. Parentheses around the authority's name and date indicate that the species was originally named in a different genus to its present generic allocation. The scientific name is followed by the publication where the species was described, and the location where the type specimen (or type series) was obtained. Most of this information is taken from Wilson & Reeder (2005).

Taxonomy This section contains information on taxonomic problems, if any, associated with the species, and its relationship with other species in the genus. For some species, there is considerable information about these topics; for others, there may be nothing. A list of synonyms (without the taxonomic authority for each) and the number of subspecies (if any) is presented, mostly taken from Wilson & Reeder (2005). The chromosome number is given if available, and in some cases this is followed by other information relevant to the chromosomes.

Description This section, together with the illustrations, provides the reader with adequate information to identify the species. The section begins with a brief overall description of the species, including an indication of size. This is followed by a detailed description of the external features of the species' head (and parts of the head), dorsal pelage, legs, feet, ventral pelage, and tail (in this order), as well as any special characteristics unique to the species. For some species, diagnostic characteristics of the skull and dentition are given. The characters described in this section are common to all subspecies of this species (unless otherwise noted). The mammary formula, i.e. the number and arrangement of nipples in adult females, is noted wherever this feature varies between the taxa being discussed.

Geographic Variation Variation within the species may be of two sorts: (a) clinal variation without subspecies, or (b) subspecific variation. If (a), there is a description of the character(s) that alter clinally across the geographic range of the species. If (b), each of the subspecies is listed with its geographic range and, where available, the characters that distinguish it from other subspecies of the species. For some species, subspecies have been described that are no longer considered to be valid; in some cases, such names may be listed but without further comment.

Similar Species Species that are sympatric or parapatric with the species under consideration, and with which it may be confused, are listed along with diagnostic characteristics (additionally, readers may refer to profiles of the similar species in question). In some instances, species that are allopatric in distribution are also included.

Distribution The first sentence 'Endemic to Africa' informs the reader that this is an African species and does not occur on any

other continent; if a species also occurs outside Africa, this is noted at the end of this section with a very brief synopsis of the extralimital range. For widespread species that generally remain so today (e.g. *Herpestes sanguineus*), the text provides a general idea of the range, highlighting only places or countries where the species may have been extirpated, recently newly recorded, or providing clarity on previously incorrectly attributed country records and range limits. In the case of widespread species that have undergone significant range contractions and declines (e.g. *Lycaon pictus*), the text generally differentiates between former and current ranges in an attempt to elucidate a clearer picture of where species do, or no longer, occur. Finally, for more range-restricted species (e.g. *Canis simensis*), the information provided may be quite precise, detailing even localized distribution within the confines of its small range. A distribution map (see below) augments the information given here.

Habitat This section provides a description of the range of habitats where the species lives. Details of plant communities, plant species, vegetation structure, soil type and/or structure and water availability, etc. (if available) are also recorded. Other information may include average annual rainfall, altitudinal limits and seasonal variation in habitat characteristics.

Abundance A general indication of abundance in the habitat. This may be unquantified, such as abundant, common, uncommon, rare, or phrases such as ‘rarely seen but frequently heard’, etc. For better-known species, abundance may be expressed as estimates of density (e.g. number/ha or number/km²), or relative abundance within the community (e.g. ‘comprised x% of carnivores captured’, ‘the second most numerous species’); for the better-known, rare species, actual numbers of individuals for the species may be given. Other information may include seasonal changes in density, frequency of observations, or the relative abundance of specimens in collections.

Adaptations This section describes morphological, physiological and behavioural characteristics that show how the species uniquely interacts with its environment, conspecifics and other animals. This section may also describe species-specific adaptations for feeding, locomotion, burrowing, mechanisms for orientation, production of sound, sensory mechanisms and activity patterns. In some instances comparison with related or convergent species allows the unique adaptations of the species under discussion to be detailed or highlighted.

Foraging and Food This section provides information on the diet and foraging habits of the species. The diet is described either by a list of the taxa of animals or plants consumed, or as a quantitative measure of the contents of the stomach or the faeces. This section can also include any of the following: location of food, foraging behaviour, times when foraging occurs and daily distance moved; hoarding; seasonal changes in diet and food availability; individual or co-operative behaviour used in foraging and hunting; sex and age differences in foraging and diet; and nomadic or migratory movements in relation to food availability.

Social and Reproductive Behaviour Topics in this section may include group structure (whether solitary, social, or colonial),

group size and composition; agonistic and amicable behaviour, comfort behaviour, etc.; home-range (including quantitative data), territorial behaviour, courtship and mating behaviour, behaviour of young, parental–young interactions; presence of helpers, vocalizations, and interactions with other species (mammals, birds, etc.).

Reproduction and Population Structure This section begins with an assessment of reproductive strategy (if known) and the times/seasons of the year when individuals are reproductively active (pregnancy and lactation in females, active spermatogenesis in males). Other information may include length of gestation, times/seasons of births, including peaks of births, litter-size, birth-weight and size, spacing of litters, growth and time to weaning, maturity, longevity, and mortality rates. Reproductive strategies, if known, are described with respect to locality, food availability, and population density. Population structure (sex ratio, adult/young ratio, abundance of different cohorts in the population at different times of the year) may be described, and related to seasonal variations in reproduction and environmental variables.

Predators, Parasites and Diseases The known predators, parasites and diseases are listed. Information on parasites and diseases is not intended to be exhaustive, but simply to provide an entry point into the literature on the topic. In some cases, information on diseases from captive animals is presented. Additional information is given if the species is a host to diseases that affect humans and domestic stock.

Remarks This subheading subsumes five of the above subheadings (Adaptations, Foraging and Food, Social and Reproductive Behaviour, Reproduction and Population Structure, and Predators, Parasites and Diseases) in those instances where there is little or no information available.

Conservation The conservation status of the species is stated, as given by the *IUCN Red List of Threatened Species* (version 2011.2). The IUCN Red List categories follow the definitions and criteria given in the *IUCN Red List Categories and Criteria Version 3.1* (Table 4). For those species classified as threatened (i.e. ‘Vulnerable’, ‘Endangered’, ‘Critically Endangered’), the criteria met are also indicated. Some species have changed status due to improved knowledge, taxonomic revision, or the impact of threatening processes or conservation actions. Readers can obtain detailed reasons for the past and present status of a species by going to the IUCN Red List website (www.iucnredlist.org). If a species was listed on Appendix I, II or III under CITES (Convention on International Trade in Endangered Species; www.cites.org; as of 22 December 2011) or Appendix I or II of CMS (Convention on Migratory Species; www.cms.int; as of 5 March 2009) this is also indicated. For some species, additional information is provided, such as presence in protected areas, major threats, and current or recommended conservation measures.

Measurements A series of morphological measurements is provided. For each species there is a standard set of measurements. The abbreviations for each measurement are given in the Glossary.

Table 4. Definitions for the IUCN Red List categories (from IUCN – Red List Categories, Version 3.1).

| Category | Description |
|-----------------------------------|--|
| Extinct (EX) | A taxon is Extinct when there is no reasonable doubt that the last individual has died. A taxon is presumed Extinct when exhaustive surveys in known and/or expected habitat, at appropriate times (diurnal, seasonal, annual), throughout its historic range have failed to record an individual. Surveys should be over a time-frame appropriate to the taxon's life-cycles and life-form. |
| Extinct in the Wild (EW) | A taxon is Extinct in the Wild when it is known only to survive in cultivation, in captivity or as a naturalized population (or populations) well outside the past range. A taxon is presumed Extinct in the Wild when exhaustive surveys in known and/or expected habitat, at appropriate times (diurnal, seasonal, annual), throughout its historic range have failed to record an individual. Surveys should be over a time-frame appropriate to the taxon's life-cycle and life-form. |
| Critically Endangered (CR) | A taxon is Critically Endangered when the best available evidence indicates that it meets any of the criteria A to E for Critically Endangered, and it is therefore considered to be facing an extremely high risk of extinction in the wild. |
| Endangered (EN) | A taxon is Endangered when the best available evidence indicates that it meets any of the criteria A to E for Endangered, and it is therefore considered to be facing a very high risk of extinction in the wild. |
| Vulnerable (VU) | A taxon is Vulnerable when the best available evidence indicates that it meets any of the criteria A to E for Vulnerable, and it is therefore considered to be facing a high risk of extinction in the wild. |
| Near Threatened (NT) | A taxon is Near Threatened when it has been evaluated against the criteria but does not qualify for Critically Endangered, Endangered or Vulnerable now, but is close to qualifying for (or is likely to qualify for) a threatened category in the near future. |
| Least Concern (LC) | A taxon is Least Concern when it has been evaluated against the criteria and does not qualify for the Critically Endangered, Endangered, Vulnerable or Near Threatened categories. Widespread and abundant taxa are included in this category. |
| Data Deficient (DD) | A taxon is Data Deficient when there is inadequate information to make a direct, or indirect, assessment of its risk of extinction based on its distribution and/or population status. Data Deficient is not a category of threat. Listing of taxa in this category indicates that more information is required and acknowledges the possibility that future research will show that a threatened classification is appropriate. |
| Not Evaluated (NE) | A taxon is Not Evaluated when it has not yet been evaluated against the criteria. |

A measurement is cited as the mean value (with minimum value to maximum value in parentheses) and sample size. For some, the standard deviation (mean \pm 1 S.D.) is given instead of the range. For most species, data for males and females are presented separately. In some cases, more than a single set of measurements is given; this is particularly the case for widespread species where geographic variation in size may be evident, and also for species with several well differentiated subspecies (in which case, we have endeavoured to present a set of measurements for each). Some

species have additional stand-alone measurements presented beneath the primary series. Skull measurements are generally not provided, with the exception of the small carnivores (Herpestidae, Mustelidae, Nandiniidae and Viverridae). The majority of measurements also contain the location(s) where the specimens were obtained, and the source of the data. Sources are either cited publications, or specimens in museums, or unpublished information from authors or others. The acronyms for museums where specimens were examined and measured are given in Table 5.

Table 5. Museum acronyms and abbreviations.

| Acronym | Museum name | Acronym | Museum name |
|---------|--|---------|--|
| AMNH | American Museum of Natural History, New York, USA | MZUF | Museo Zoologico de 'la Specola', Firenze, Italy |
| BMNH | Natural History Museum, London, UK [formerly British Museum (Natural History)] | NHMB | Naturhistorisches Museum, Berlin, Germany |
